External supplemental overload devices are shown in Figure 37-32. These devices provide either current protection or current temperature protection. The bimetallic disk overload protector is widely used in the protection

(b)

(a)

(c)

Figure 37-32 (a) External-type compressor overload; (b) Klaxon current and temperature protector can be located inside or outside of the compressor; (c) when it is located outside of the compressor, it is under the motor terminal cover; (d) (see page 602) this motor cover holds it tightly against the compressor so it can sense the motor's temperature.

(d)

Figure 37-32 (Continued)

of electrical motors. When the temperature is raised, the disk will warp and break the electrical circuit. The external device is mounted on the motor shell and resets automatically when the temperature returns to normal.

Many current overload devices sense both the current and temperature of the motor. These devices, like those located within the Bakelite cover of small compressors, must be in their enclosure to function properly. If the Bakelite cap is left off, then the overload will only sense the current and not the temperature. This reduces their sensitivity and removes a large portion of the overload safety protection from a motor. The current-temperature device is usually connected for **line duty**, but some versions are used for **pilot duty**. A three-phase overload device is shown in Figure 37-33.

Internal Current and Temperature Device

Another device that is sensitive to both internal current and temperature and is wound into the motor windings is the internal line-duty overload device (Figure 37-34). As the

Figure 37-33 Three-phase overload.

Figure 37-34 Internal motor overload.

overload occurs, the bimetal strip within the device warps to open the contacts. The internal device is wound into the motor windings and automatically resets when the motor cools down.

CAUTION

Many blower and compressor motors do not have manual reset for thermal overload. Always make sure that the motor has cooled down to allow any internal devices to reset before testing. Testing for an open winding on a motor may lead to inaccurate readings if the internal thermal overload device is tripped.

Thermal Overload Relay

A thermal overload relay is current sensitive with automatic reset and is connected in series with the motor winding. On an increase in heat due to excessive motor current, the upper bimetal strip will warp, opening the pilot-duty contacts wired in series with the contactor. Reset is automatic upon cooling. The lower bimetal strip prevents nuisance trip-outs caused by high ambient temperature.

Heater Element Current Overload

A heater element current overload device for pilot duty uses a bimetal element (spiral or disk type) that responds to heat generated by a heater element. When the bimetal heats sufficiently, the contacts open, disconnecting the contactor. It automatically resets on cooling. The heater elements are interchangeable and calculated for a specific range of current. They should be matched to the motor current.

Another version of this same device uses a solder pot relay instead of a bimetal sensing element. The solder pot relay has a ratchet-and-spindle construction and requires manual reset. It uses interchangeable heaters similar to the bimetal overloads. Heaters are not interchangeable between different makes of equipment.

Magnetic Overload

The magnetic overload is a current sensitive device. A core placed inside a coil will attempt to center itself in the magnetic field created when current flows through the coil. The sensing coil is wrapped around a sealed tube filled with silicone oil containing the core. Excessive current will pull the core toward the armature, causing the contacts that are attached to the armature to open. The silicone has a dampening effect, which prevents operation of the device for temporary overload conditions, such as those that occur on startup. Current rating is fixed and cannot be field adjusted.

General Electric Thermotector

The General Electric Thermotector device is also an internally actuated temperature motor protector. On this device the case and the internal strip expand at different rates. The device will trip early if the temperature rises rapidly. If the temperature rise is gradual it will trip at its normal setting. This means it is a rate-compensated device.

37.14 MOTOR CIRCUIT TESTING

Since motors are so important in HVACR systems, they are carefully protected and can be thoroughly tested to see that they are operating properly. The tests that follow begin with single-phase motors. Since many single-phase motors require capacitors, a word of warning needs to be added about handling capacitors. Capacitors can be dangerous. Safety precautions are required.

SAFETY TIP

Capacitors can hold a high-voltage charge even after the power is turned off. Always discharge capacitors before touching them.

TECH TIP

Capacitors should be discharged before you work on the system; however, the capacitor needs to be discharged with a bleed resistor. If the capacitor is discharged with a screwdriver or other metal device touching the two terminals, the spark that is generated externally can also occur internally, damaging the capacitor.

A variety of instruments can be used for testing motors. The megohmmeter (Figure 37-35) is used to check the resistance of the motor windings. Clamp-on ammeters are used to measure the current in the circuit. In addition to these, voltmeters are used to measure the operating voltages, and capacitor analyzers are used to measure the actual mfd rating of the capacitor.

The first thing to do whenever testing any motor is to make sure that the power supply to the motor has been secured. The motor windings can be checked with a multimeter (Figure 37-36). It may be necessary to remove a guard

Figure 37-35 Megohmmeter. (Courtesy of Extech Instruments, A FLIR Company)

Figure 37-36 To test motor windings, first remove the leads.

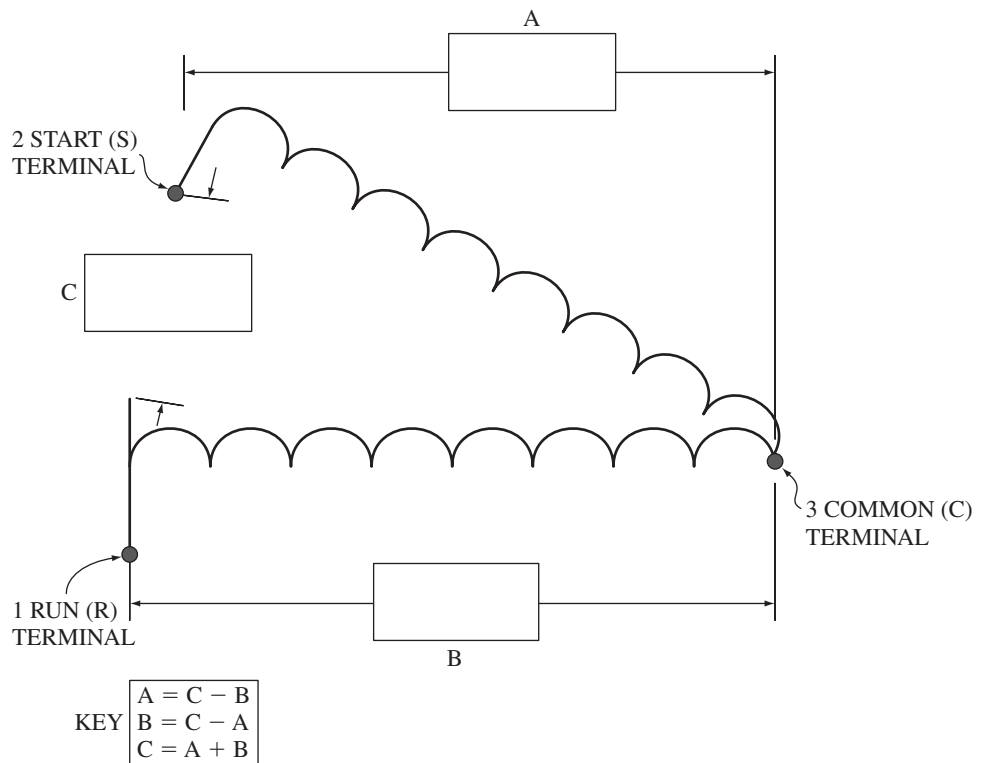

that encloses the terminals on a hermetic unit. The terminals should be marked C (common), S (start), and R (run).

CAUTION

Occasionally the terminal has been damaged, and on a pressurized system the terminal can blow out. To avoid possible injury, unless the charge has been removed, use terminal points some distance away from the compressor when checking compressor motor resistance. Be sure that all accessories such as capacitors and relays are disconnected.

Use an ohmmeter to read the resistance in both the run and start winding. Be sure good contact is made with the proper terminals.

Figure 37-37 Method of determining run, start, and common motor terminals.

If the terminals are not marked, they can be identified by a simple test. First, measure the resistance between each pair of terminals. For example, assume that these readings are $5\frac{1}{2}$, 4, and $1\frac{1}{2}\Omega$. By diagramming them as shown in Figure 37-37, the terminals can be identified. In the example, the greatest reading is between 1 and 2. The common terminal is therefore 3, the one not being touched. So terminal 3 is C. Then, reading from C, the greatest resistance is to 2. Therefore, 2 is S. And, finally, since 2 is S and 3 is C, 1 must be R.

The motor is then tested for an open winding, a broken wire, or a shorted winding, as shown in Figure 37-38. To do this, a good low-range ohmmeter ($R \times 1$) is required. A zero resistance means a shorted winding. Low resistance means the winding is good. An infinity reading means it is an open winding. As a rule, the start winding has a resistance 3–5 times the resistance of the run winding.

Large motors (5–10 hp and higher) have heavy copper windings to carry the motor current. They may therefore indicate a reading very close to a short when winding resistance is read, depending on the ohmmeter.

Figure 37-39 shows the motor being tested for a grounded winding. One lead is placed in contact with bare metal on the compressor casing. For this application, the ohmmeter needs to be capable of measuring very high resistance ($R \times 100,000$). For an ungrounded winding, the resistance is generally 1–3 M Ω (megaohms). This applies to both single-phase motors and three-phase motors.

Figure 37-38 Method of testing open, shorted windings and broken wires.

37.15 INSULATION RESISTANCE TESTERS

Electrical insulation is classified by the temperature stability of the materials that are used for the winding. As an example, hermetic compressor windings are generally rated for class H (180°C or 356°F), Table 37-2. Windings of this type are composed of materials that have an acceptable thermal life expectancy at this temperature. Examples of insulating materials for this temperature range are silicone elastomers, mica, glass fibers, and polymers. The insulated windings will often have a varnish or polyester-base

SERVICE TIP

The temperature of the compressor is important in testing for a partially grounded winding. If the compressor will run, it should be run for about 5 min before testing.

(a)

(b)

Figure 37-39 Testing for a grounded wiring: (a) not grounded; (b) grounded.

Table 37-2 Motor Insulation Temperature Classification

Class	°C	°F
Class 90 (O)	90	194
Class 105 (A)	105	221
Class 130 (B)	130	266
Class 155 (F)	155	311
Class 180 (H)	180	356
Class 220	220	428
Over class 220 (C)	>220	>428

top coat. When exposed to high temperatures over time, the insulation begins to break down. Hairline cracks can form in the top coat, which can absorb dirt and moisture. Insulation testing helps to determine the level of insulation breakdown for motor windings over time. The motor is first

tested when it is new and then at regular intervals during its useful life of operation.

These are special testers that are invaluable for testing leakage resistance from motor windings to ground. They are often used to periodically test semihermetic motor insulation. The meters can test leakage at high voltage (500 V for 208–240 V motors and 1,000 V for 480 V motors). They may be battery operated or use a hand-cranked generator and are often referred to as meggers because they must be able to read resistances of tens of millions of ohms (megohms). They may detect insulation faults, where an ordinary multimeter using a few volts DC would show a satisfactory reading.

SERVICE TIP

The wiring that is used for motor windings is insulated with a thin coat of varnish. As the motor is used and the windings are heated, this material will slowly carbonize. As it carbonizes, it will slightly change to a darker tan and eventually to black. When it is completely carbonized, it does not provide any insulating capacity. As a motor heats up, this breakdown process can be accelerated to the extent that in extreme conditions it can carbonize almost immediately when overheated. A megger tests for the degree of breakdown in the insulation. This also provides an indication of the useful life that may remain with a motor or compressor.

SAFETY TIP

When testing for a grounded winding, one test lead is placed on the terminal and the other on the outer shell of the compressor. Be careful to make good contact with the motor shell. A coat of paint or a layer of dirt can hide a grounded winding. The copper refrigerant lines may also be used to check for grounds.

The windings of a three-phase motor all should have the same resistance. Remember when checking a three-phase motor to be sure to reconnect it in the same manner as originally connected. Interchanging any two connections can reverse the rotation of the motor.

37.16 GENERAL ELECTRIC MOTORS (ECM)

ECMs were developed by the General Electric Corporation in the mid-1980s (Figure 37-40). ECM stands for electronically commutated motor. They were originally used as blower motors, but today they are used for every motor need, including combustion air-blower motors, condenser fan motors, and compressor motors. These motors are ultra-high efficiency, programmable, brushless DC motors, 120 V or 240 V AC input. They utilize a permanent magnet rotor and a built-in AC-to-DC inverter to produce the direct current that operates the motor (Figure 37-41).

Figure 37-40 GE ECM motor.

Figure 37-41 Cutaway of GE ECM motor.

Figure 37-42 Cutaway of GE ECM motor showing ball bearings.

ECMs have a number of advantages, as follows:

- **High efficiency** ECMs are approximately 70 percent efficient as compared to 45 percent or less for PSC motors.
- **Low maintenance** ECMs use ball bearings as opposed to sleeves, which are used on PSC motors (Figure 37-42). Ball bearings are permanently lubricated as compared to sleeved motors, which must be routinely lubricated.
- **Speed control** ECMs come preset for a specific cfm requirement. Because the rpm of dc motors is more easily adjusted, ECMs can be field adjusted to a specific cfm and with the addition of a controller can be remotely controlled using a central energy-management program (Figure 37-43).
- **Constant CFM** ECMs are designed to provide a constant CFM over a wide range of static pressures.

Figure 37-43 ECM motor controller PC board.

The ECM rpm will increase automatically to provide the designed airflow.

- **Heat load** ECMs operate at almost ambient temperatures, as compared to PSC motors, which typically operate from 90° to 150° above ambient.
- **Soft start** ECMs are designed to start at a low rpm and gradually ramp up to the designed speed. This places less stress on the motor fan and other mechanical parts as compared to the almost instant starting of a PSC motor. Soft starting also decreases the sometimes-noticeable blast of air from conventional blowers associated with PSC motor starting.
- **Flexibility in size** Because the ECMs' rpm can so easily be controlled without the loss of efficiency, it is possible for manufacturers to use a limited number of various horsepower-rated ECMs throughout their entire production line. This reduces inventory costs for the manufacturer and for the service company by reducing the number of replacement motors that they must carry on their service vehicles.

ECM X13

This motor is used for indoor blower applications and was developed to meet the 13-SEER mandate for residential air-conditioning units that went into effect in 2006. The X13 offers up to 33 percent greater efficiency than a PSC at rated speed and up to 200 percent in constant fan mode. It allows for variable speed operation from 600 to 1,100 rpm, has up to five selectable constant speed torque settings controlled by 24 V AC inputs, five fixed speeds, and improved high-static CFM performance.

The major difference between the X13 and PSC motors is the ability to deliver constant torque. With standard PSC motors, as the air static pressure increases, both the motor torque and CFM delivered will decrease. The X13 maintains the torque it was programmed for, and although the CFM delivered will still decrease with an increase in static pressure, it will be less as compared to a PSC.

ECM 2.3

The ECM 2.3 is a premium programmable motor that can operate over a wide range of speeds from 200 to 1,300 rpm. This type of motor can deliver constant airflow over a wide range of external static pressures. As an example, if the media filter becomes dirty, this motor will automatically ramp up to ensure that the programmed amount of airflow is still delivered. These are the quietest motors because they ramp up and down slowly. The added benefits for this type of motor also increase its initial cost.

Premium ThinkTank ECM

Premium ThinkTank ECMs have the highest efficiency and advanced features like self-adjusting constant airflow, climate-specific operating profiles, fully variable speed range, and digital communication. This enables true plug-and-play self-recognition software and a user interface that can control system setup and troubleshooting. The OEM control board can automatically recognize the connected units to adjust the required airflow for heating, cooling, and zoning.

37.17 ECM OPERATION

ECMs consist of a motor and a control module (see Figure 37-40). The rotor of the ECM is a permanent magnet, and the stator is wound like a three-phase motor (see Figure 37-41). The module controls the speed and rotation of the motor by energizing the windings in sequence, creating a rotating magnetic field. The permanent magnets in the rotor follow this rotating magnetic field. No more than two windings are energized at one time, leaving one set de-energized. The module checks the speed and rotation of the motor by reading the voltage induced in the windings that are not energized. The motor periodically checks the work load on the motor by not energizing any windings and measuring how much the motor slows down in a fixed period of time. This allows the module to calculate at what speed the motor must turn to provide the amount of airflow it is programmed for. The modules are programmed for the specific blower and unit the motor is matched with. ECM blowers do not have a preset rpm; their speed is variable between 200 rpm to 1050 rpm, with a safety limit of 1,500 rpm. The speed that a motor operates at is determined by its programming, the control signals it receives, and the resistance across the blower.

HVACR equipment uses blower control boards to control ECM operation (Figure 37-44). ECMs are made for three types of controls: pulse-width modulation, 24 V thermostat signals, or a digital serial interface. With pulse-width modulation, the control is not looking for the presence or absence of a particular voltage but is measuring the length, or "width," of a series of voltage pulses. Longer pulses call for increased rpm; shorter pulses call for decreased rpm. Thermostat control looks for 24 volts on pins that represent preprogrammed airflow requirements. Thermostat control is the most common. Digital serial controls are the newest of the three control methods. The unit communicates with the motor control using serial communication.

Figure 37-44 ECM motor control board showing speed jumpers.

Figure 37-45 ECM motor connectors.

37.18 ECM SERVICE

ECMs have two electrical connections: a power connection and a control connection (Figure 37-45). Power is supplied to the power connection all the time, even when the motor is not running. Power to the unit should always be turned off when disconnecting or connecting the power plug. Plugging or unplugging the power plug with power on will cause a high current arc that can damage the motor module. The easiest way to check an ECM is to use a service tool that plugs into the control port to control the motor. Figure 37-46 shows a simple device that can be used to check the operation of an ECM. If the motor will operate using the tester, the problem is in the wiring harness or blower control board. If power is available at the power connector and the motor will not operate using the tester, the problem is most likely the motor control module. Control modules are replaceable without replacing the entire motor (Figure 37-47). The motor windings can be checked by removing the module from the motor and checking their resistance. They should ohm out like a three-phase motor, with all the windings having the same resistance, which should be less than 20 ohms. If the windings are good, the module is bad. Be certain to get the correct module, because the modules are specific for the unit the blower is on.

37.19 VARIABLE-FREQUENCY DRIVES

The speed of an AC motor is dependent on the number of stator poles and the frequency of the current. Multispeed AC motors designed to operate on constant-frequency (60 Hz)

Operation	Test Mode	Switch Selections					Expected Result of Typical System
		CONT FAN	HEAT	COOL	SK PWR		
TSTAT	Fan-only	ON	OFF	OFF	OFF		Motor runs at fan airflow
	Heating	ON	ON	OFF	OFF		Motor runs at Heating airflow (higher than Fan only)
	Cooling	ON	OFF	ON	ON		Motor runs at Cooling airflow (higher than Fan only)
	Dehumidify	ON	OFF	ON	OFF		Motor runs at Dehumidification airflow (lower than cooling airflow)
VSPD	Variable Spd	ON	OFF	OFF	ON		Motor runs at 50% airflow
DSI	Digital Ser. Int.	ON	OFF	OFF	OFF		Motor runs at Fan airflow

INSTRUCTION ON BACK OF MOTOR TESTER

Figure 37-46 ECM motor tester.

Figure 37-47 ECM motor replaceable module.

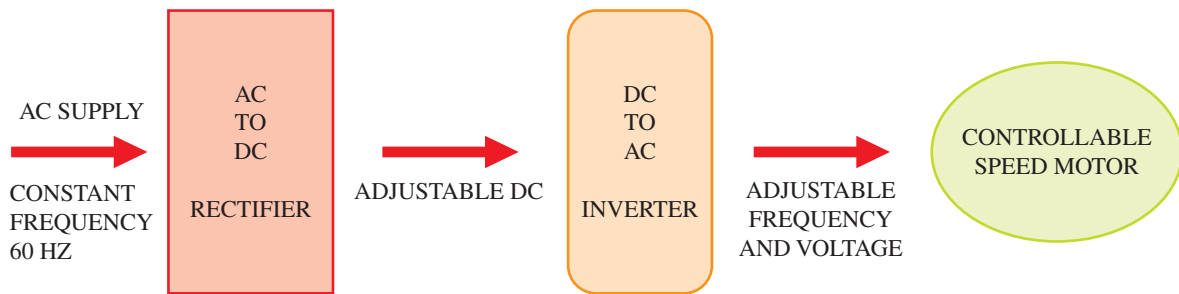

Figure 37-48 Basic configuration of a variable-frequency drive.

systems are provided with stator windings that can be reconnected to form different numbers of poles. A two-speed motor will have a winding that is switched to provide for either full speed or half speed. A four-speed motor will have two windings that each provide for two speeds when switched. This type of motor speed control is suitable for equipment that requires several definite speeds but not necessarily a continuously adjustable speed drive.

A variable-frequency drive (VFD) is a system for controlling the rotational speed of an electric motor by controlling the frequency of the electrical power supplied to it. Drive controllers are solid-state power conversion devices. The usual design first converts AC input power to intermediate power using a rectifier. The DC intermediate power is then converted to quasi-sinusoidal AC power using an inverter switching circuit.

VFDs for AC motor speed control are becoming more commonplace for variable-speed blower and compressor drives. In the past, solid-state motor controls were not cost effective for many applications. However, with the increased focus on efficiency, variable-frequency drives can recover their initial cost over time through reduced electrical operating expenses.

The basic concept of a VFD is shown in Figure 37-48. A solid-state rectifier is used to convert the line frequency AC into DC. The DC power is then converted back into adjustable-frequency AC power through a solid-state inverter. The reason for the VFD is to control the frequency of the AC power. Adjustment of the AC frequency will allow for motor speed control. This speed control is not a step type of control as delivered by changing the configuration of the stator poles. Instead, it is a fully variable speed control that may be continuously adjusted through the use of solid-state devices. Typically this type of drive will generate a considerable amount of heat, and some type of cooling will need to be employed during operation.

UNIT 37—SUMMARY

Motors are used to power compressors and fans that are commonly found in air-conditioning and refrigeration systems. Smaller residential units often use single-phase motors. Many of these utilize start and run capacitors to increase starting torque and to provide better running characteristics. Larger systems often use three-phase motors

that do not require capacitors in their circuits. Three-phase motors will draw less current for the same load range as single-phase motors.

It is important to understand how to test a motor circuit. Wiring diagrams are generally supplied by the manufacturer of the unit. These are helpful when testing starting relays. Be sure to always discharge any capacitors before working on a circuit. New electronically commutated motors are growing in popularity because they offer the advantage of variable speeds with higher efficiencies as compared to conventional motors. Motor insulation should be tested on a regular basis with a megger to help determine the extent of insulation breakdown over time. The ability to properly maintain and troubleshoot electric motors is a basic requirement for HVACR technicians.

WORK ORDERS

Service Ticket 3701

Customer Complaint: No Air Flow

Equipment Type: Light Commercial Rooftop Air Conditioner

The building contractor calls the dispatcher to complain about the newly installed rooftop air-conditioning unit. The building is nearing completion, and when the rooftop air-conditioning unit was started, no air flowed from the supply registers. The technician arrives and finds access to the roof and the unit. The technician removes the panel to access the supply fan and secures the panel so that it will not blow from the roof.

The fan is operating, but the technician immediately notices that the fan is spinning in the wrong direction. This is a three-phase motor. The technician secures the power going to the unit at the disconnect switch. The junction box for the motor leads is opened and the technician uses a multimeter to check and make sure that the circuit is not energized. There is no measured power, so the technician switches two of the three main power leads to the motor. After completing this, the disconnect switch is closed and the fan is now running in the proper direction and supplying air to the building.

Service Ticket 3702**Customer Complaint: Not Working****Equipment Type: Window Air-Conditioning Unit**

The customer brings a small window air-conditioning unit into the refrigeration shop and explains that his son, who is taking electrical classes, recently replaced a component and now the unit does not work at all. The technician working in the shop looks the unit over and notices that it has a run capacitor mounted on the frame of a hermetic compressor and sees that it appears new. Pulling a technical manual from the shelf, the technician looks up the specifications for the unit. The replaced capacitor is the wrong type. Most likely the motor became overheated and is now damaged. The technician tells the customer that he needs to discharge the capacitor and then check the motor windings with an ohmmeter, but it is suspected that the unit is damaged beyond repair.

Service Ticket 3703**Routine Maintenance****Equipment Type: Light Commercial Walk-in Cooler Three-Phase Motor**

The technician is performing a monthly maintenance call at a small family-owned grocery store. One of the items on the checklist is to test the insulation on the compressor motor. The power to the unit was shut off with the circuit breaker located in the electrical panel near to the unit. This is an older nonhermetic unit, so the motor is separately coupled to the compressor. The technician uses a multimeter to double-check that the circuit is deenergized at the motor controller before opening up the junction box. Satisfied that the circuit is de-energized, the technician connects one end of the megger leads to bare metal on the motor frame and then the other end to one of the disconnected motor leads. The three windings are checked in this manner

one at a time and the readings recorded. It is obvious in comparing the continually decreasing readings taken over time that the motor will soon need to be replaced. The technician explains to the owner that the motor will need to be replaced soon. Another option is to consider replacing the old compressor with a newer, more efficient semihermetic unit.

UNIT 37—REVIEW QUESTIONS

1. What is meant by motor torque?
2. What are two principal parts of a motor?
3. How is the speed of a motor determined?
4. How are capacitors rated?
5. What is a common application for capacitors in electric motors?
6. List the most common types of single-phase motors.
7. What are the two ways that the start capacitor can be removed from the circuit?
8. What advantages do three-phase motors have over single-phase motors?
9. What is the most common cause of motor failure?
10. According to Table 37-1, what is the upper and lower limit of a motor with the voltage of 460 V?
11. What happens if there is single phasing of a three-phase motor?
12. List the three types of protective devices used to protect the motor against excessive heat.
13. Where is the line-duty device commonly located?
14. What is the advantage of manual reset?
15. What does an external supplemental overload device provide?
16. What is the first thing to do in testing any motor?
17. What are insulation resistance testers?
18. What are ECM motors?
19. What are the principle advantages of ECM motors?
20. What is a VFD, and what is it used for?

UNIT 38

Electrical Diagrams

OBJECTIVES

After completing this unit, you will be able to:

1. identify symbols used for common electrical components.
2. explain the characteristics of different types of electrical diagrams.
3. interpret different types of electrical diagrams.
4. trace an electrical circuit on a ladder diagram.
5. draw a ladder-type diagram.

38.1 INTRODUCTION

Any successful service technician will tell you that understanding electrical circuitry is the single most important aspect of service and that understanding electrical wiring diagrams is the key to understanding electrical circuits. The goal for the technician is to understand how the system operates by studying the system's electrical diagrams.

One difficulty many technicians face when learning to read diagrams is that no two manufacturers use the same format for their wiring diagrams. Terminology and symbols can be confusing. For example, four different symbols are commonly used by manufacturers to represent a relay coil. However, there are enough common practices that learning one manufacturer's diagrams will make reading another manufacturer's diagrams easier. The more diagrams a technician reads, the better he or she will get at reading all diagrams.

38.2 SYMBOLS FOR ELECTRIC COMPONENTS

The electrical components used in air conditioning are represented by graphic symbols in wiring diagrams. These symbols may not look very much like the actual physical component they represent. Instead, they show the electrical properties of circuit components. For example, symbols for switches often show that they can break the circuit. The symbol for a common switch is usually drawn open. Symbols for loads usually look continuous, as in the symbol for a heater (Figure 38-1). Many electrical devices consist of a single-circuit component, and so they are represented by a single symbol. A pressure switch is a good example. It only wires into one circuit and is represented by one symbol (Figure 38-2). Other devices contain more than one electrical component and wire in more than one circuit. Because they are part of more than one circuit, multiple symbols are used to represent a single device. Relays are a good example. A relay consists of a magnetic coil and one or more sets of contacts. The magnetic coil is a load and is represented by a symbol for a magnetic coil. The relay contacts are a switch and are represented by a set of parallel

Figure 38-1 Heater symbol.

Figure 38-2 Pressure switch symbol.

Figure 38-3 Relay and symbols.

lines. Figure 38-3 shows a relay, the symbol for the relay coil, and the symbol for the relay contacts. Even though the relay is a single physical device, it has two electrical components that are in two separate circuits.

38.3 THE POWER SOURCE

A basic electrical circuit is made up of a source of electrons, a path for electron flow, and a load. The source provides the electromotive force to move the electrons through the circuit, the path for the electrons is provided by wires, and the load turns the electrical flow into useful work. Switches are added to control the operation of the circuit. In electrical diagrams, the source, load, and switches are all represented by graphical symbols. The wires that provide the path are represented by lines. Figure 38-4 shows a basic electrical circuit consisting of a source, a path, a load, and a switch.

Electronic circuits and battery-powered devices usually have a direct current (dc) power source. Batteries and dc power sources are drawn to represent a battery's cathode (positive terminal) and the anode (negative terminal) (Figure 38-5). The power source for most HVACR systems is either single-phase alternating current (ac), or three-phase alternating current. The power source is often shown as

Figure 38-4 Basic circuit with source path and load.

Figure 38-5 Battery symbol with anode and cathode labeled.

an electrical disconnect switch with fuses. The specifications are written by the switch, including voltage, phase, and frequency. A double-pole, single-throw switch is used for single-phase systems; a triple-pole, single-throw switch is used for three-phase systems (Figure 38-6).

SINGLE PHASE DISCONNECT SWITCH

THREE PHASE DISCONNECT SWITCH

Figure 38-6 Single-phase and three-phase disconnect switch symbol.

Figure 38-7 Transformer symbol.

Many HVACR system controls operate on a lower voltage than the line voltage. These systems require a transformer to transform, or change, the line voltage to a lower control voltage. Residential equipment uses 24 V AC for control voltage. Commercial equipment may have more than one control voltage. Commercial units frequently have both 24 V AC and 120 V AC controls, requiring two transformers. Transformers are drawn using two parallel lines to represent the iron core of the transformer, with a coil of wire on either side of the parallel lines to represent the primary and secondary windings (Figure 38-7). Transformers can be designed to accommodate different primary voltages by having multiple wires, or taps, on the primary side. These are shown as extra wires coming from the primary winding, with the different primary voltages labeled (Figure 38-8).

CODE BOX

The notes in most diagrams specify that all control wiring comply with NEC Class 2. Class 2 circuits may not be over 30 V or 100 volt-amperes, VA. This limits the power of the circuit to a level that is not likely to create fires or cause electrical shock.

Figure 38-8 Dual-voltage transformer symbol.

Figure 38-9 Light and symbol.

38.4 SYMBOLS FOR LOADS

A load creates a voltage drop when current passes through it. Loads use the electrical energy to perform work. Common loads are lights, heaters, and motors. A light is represented as a circle with rays radiating from it. Often, a letter inside the circle will represent the light's color (Figure 38-9). Electric heaters operate through resistance. Heat is created when current passes through the electrical resistance, creating a voltage drop and turning the electrical energy into heat. This is why the symbol for a resistor and the symbol for an electric heater are identical (see Figure 38-1). In air-conditioning diagrams, the symbols for heaters often have letters labeling them to help identify their function, such as CH for crankcase heater (Figure 38-10). Electromagnetic coils are another common type of load. They turn electrical energy into magnetism. There are several symbols used for magnetic coils, including a circle, a diagonal line connected to two smaller diagonal lines, a rectangle, and a series of loops (Figure 38-11). Because many electrical devices in HVACR contain magnetic coils, these symbols can be found representing different kinds of components, including solenoid valves, magnetic overload coils, relay and contactor

Figure 38-10 Crankcase heater and symbol.

Figure 38-11 Magnetic coil symbols: diagonal, circle, windings.

Figure 38-12 Devices represented by a magnetic coil: solenoid, overload, motor, relay coil, and contactor coil.

coils, and motors. Figure 38-12 shows some different components that can be represented by a magnetic coil.

SAFETY TIP

There should always be a load in any path between L1 and L2. Any path that can be traced from L1 to L2 should pass through a device that uses power, like a motor or heater. A path that does not include a load is called a short circuit.

38.5 MOTORS

Motors are the main loads shown in most air-conditioning diagrams. Because there are a variety of motors used in HVACR, there are a variety of symbols used to represent them. Motors are usually shown as a circle, a coil of windings, or a combination of the two. A simple shaded pole motor is usually shown as a circle with two leads coming out (Figure 38-13). Motors with more than one winding will have three or more leads. They often show the windings inside of a circle. Single-phase motors that have both a start and a run winding will show both windings and three leads (Figure 38-14). Three-phase motors also will show three leads, but they have three internal windings instead of two (Figure 38-14). Some motor symbols show only the windings without the circle, while others will simply be circles with leads and no windings showing (Figure 38-14).

Many motors have internal thermal overloads that break the circuit inside the motor if the motor overheats. These are drawn inside the circle in series with the motor windings. Figure 38-14 shows examples of symbols for motors with internal overloads.

Motors are often labeled with letters representing their function. For example, IFM for indoor fan motor or CFM

Figure 38-13 Shaded pole motor symbol.

for condenser fan motor. Compressors use a special type of motor symbol because they have external terminals for connection instead of wire leads. These terminals are usually shown on the symbol (Figure 38-14).

Many single-phase motors require capacitors to operate. These include permanent split capacitor motors (PSC), capacitor start motors (CS), and capacitor start run motors (CSR). Capacitors are always drawn outside the motor. They are usually shown as two parallel lines: one straight and the other curved. Sometimes the capacitors are shown as a circle or an oval with the parallel lines inside the oval (Figure 38-15).

Figure 38-14 From left to right: Motor with start and run winding inside circle; Three-phase motor inside circle; Motor with internal overload; Three-phase motor winding; Compressor motor with common start and run terminals; Two-speed motor.

Figure 38-15 Capacitors and symbols.

38.6 SYMBOLS FOR SWITCHES

A switch controls a load by opening or closing the circuit to the load. Switches control loads by making a hole in the circuit. This is why symbols for switches often show how they break the circuit. For example, a simple single-pole toggle switch is drawn to look like the early knife-blade switches (Figure 38-16). When a switch is opened, it breaks the circuit and does not allow current to pass through. When a switch is closed, a path is created for

Figure 38-17 Comparison of single- and double-pole switch symbols.

current to flow (Figure 38-16). There should be no voltage drop through a switch when current flows through it.

The two most common types of mechanical switches used today are toggle switches and pushbutton momentary switches. A toggle switch alternates between two conditions—for example, off and on. The light switches in your house are toggle switches. Toggle switches are identified by their number of poles and throws. The number of poles identifies how many circuits a switch can handle, while the number of throws identifies the number of possible paths for each circuit. A switch that can only switch a single circuit is called a single-pole switch, while a switch that can switch two circuits simultaneously is called a double-pole switch (Figure 38-17). A switch that has only one possible path for each circuit is called a single-throw switch. A switch that has two possible paths for each circuit is called a double-throw switch (Figure 38-17). These terms are combined to identify switches as

- Single-pole, single-throw (SPST)
- Single-pole, double-throw (SPDT)
- Double-pole, single-throw (DPST)
- Double-pole, double-throw (DPDT)

Figure 38-17 shows the symbols for these switches.

Unlike toggle switches, momentary pushbutton switches only hold their new position while they are being pushed and then return to their original position. The position the switch is in when it is not being pushed is called its normal position. Pushbutton switches can be either normally open or normally closed. A normally open switch starts out open, makes the circuit when it is pushed, and then returns to the open position when it is no longer being pushed. Normally open pushbutton switches are drawn above the line, as in Figure 38-18. A normally closed switch starts out closed, breaks the circuit when it is pushed, and then returns to the closed position when it is no longer being pushed. Normally closed pushbutton switches are drawn below the line, as in Figure 38-18. Start-stop switches and stop, forward, reverse switches are examples of momentary pushbutton switches (Figure 38-19).

Figure 38-16 Knife-blade switch and symbol; Knife-blade switch in both positions with and without current flow.

38.7 CONTROLS

A control is a switch in an HVACR system that opens and closes in response to a system condition to control the operation of the unit. Controls can regulate the normal operation of the system or monitor system operation for unsafe operating conditions. Controls are drawn like a toggle switch

Figure 38-18 Normally closed (NC) pushbutton switch; Normally open (NO) pushbutton switch.

with a stem under the switch connected to a symbol that represents the sensing mechanism. For example, thermostats look something like a bimetal (Figure 38-20), and pressure switches look like a small bellows (see Figure 38-2).

These switches either close on rise or open on rise. Close-on-rise switches are drawn below the line; open-on-rise switches are drawn above the line. A cooling thermostat that controls an air conditioner would be a close-on-rise switch, closing to energize the circuit when the temperature rises above the thermostat set point. A heating thermostat that controls a furnace would be an open-on-rise switch,

Figure 38-19 Start-stop switch.

Figure 38-20 Thermostat and symbol.

opening to de-energize the circuit when the temperature rises above the thermostat set point (Figure 38-21).

Figure 38-22 shows the symbols for several common HVACR controls, including the following:

- Thermostats that open and close in response to temperature change
- Pressure switches that open and close in response to pressure change
- Humidistats that open and close in response to humidity change
- Flow switches that open and close in response to change in air or water flow
- Float switches that open and close in response to change in liquid level

Figure 38-22 Symbols for thermostats, pressure switches, humidistats, float switches, flow controls.

38.8 SYMBOLS FOR RELAYS AND CONTACTORS

Relays and contactors are essentially electrically operated switches. They are composed of two electrical devices: a coil and a set of contacts. The coil is an electrical load; the contacts are switches. The coil produces a powerful magnetic field when it is energized. This magnetic field attracts a steel bar that is connected to a set of contacts. When the coil is energized, the magnetic field pulls the contacts, causing them to change position. The coil and contacts are in separate electrical circuits and have their own symbols. Because the coil and contacts are not drawn together and are often in completely different parts of the diagram, the coil and contacts are labeled to identify which contacts are controlled by which relay coil (Figure 38-23). A contactor is essentially a larger version of a relay. Contactors typically handle larger current than relays. The symbols for relays and contactors are identical.

Four different symbols are commonly used by different manufacturers to represent a relay coil, including a circle, a diagonal line connected to two smaller diagonal lines, a rectangle, and a series of loops. Figure 38-24 shows the different symbols that are commonly used to represent relay coils.

Relay contacts can be either normally open or normally closed. A normally open set of contacts will close to complete a circuit when the relay coil that controls them is energized. Normally closed contacts will open to break a

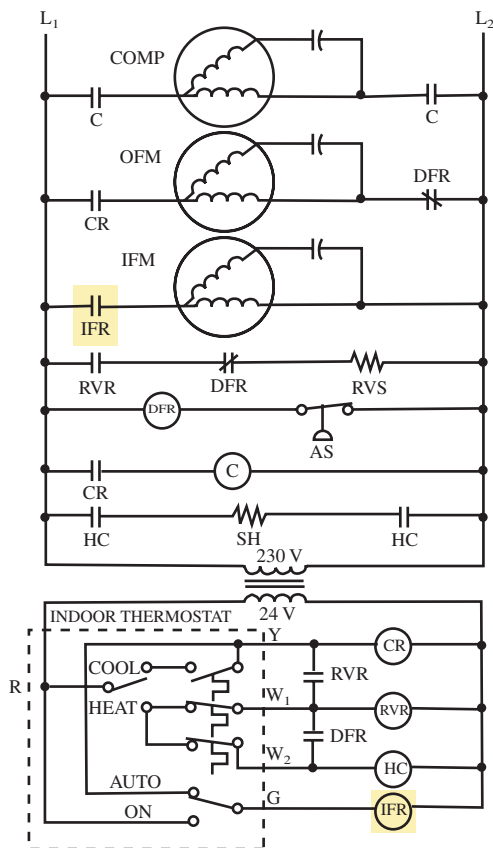

Figure 38-23 The coil of the fan relay is located in the 24 V portion of the diagram, while its contacts are located in the line-voltage portion.

Figure 38-24 Different symbols for relay coils.

circuit when the relay coil that controls them is energized. It is important to understand that the contacts move when the coil is energized, not when the contacts are energized. Normally open contacts are drawn as two parallel lines. Normally closed contacts are drawn as two parallel lines with a diagonal line through them. Figure 38-3 shows the symbols used for normally open and normally closed relay contacts. It can be difficult to identify what the terminals on a relay are connected to because relays are usually encased in plastic boxes, hiding all the internal parts. Relays often use a small diagram on the side of the relay to identify the relay terminals. Some relays have the symbols for normally open and normally closed contacts molded into the body of the relay to identify the contacts (Figure 38-25).

Figure 38-25 Diagram molded into brown relay.

Figure 38-26 Symbols for fuses.

38.9 FUSES AND OVERLOADS

Overloads are controls that open to shut off a circuit if the load is drawing too much current or is overheating. Fuses are the simplest type of overload. They are drawn in series with the circuit they are protecting. Common symbols for fuses include a wavy loop resembling a sine wave and a rectangle that looks like a cartridge fuse (Figure 38-26).

Overloads can be either line duty or pilot duty. A line-duty overload breaks the line voltage circuit to the load it is protecting. When the overload senses too much current or heat it opens, breaking the circuit to the load. A pilot-duty overload has a coil and a set of contacts like a relay. The coil is in series with the load being protected, and the contacts are in series with the coil for the control that normally operates the load, such as a contactor. When the overload senses too much current or heat, the overload contacts break the circuit to the contactor coil. The contactor coil is de-energized, opening the contactor contacts, breaking the circuit to the load. Figure 38-27 shows a diagram of a pilot-duty overload relay.

Overloads sense the current by either heat or magnetism. Heat-sensing overloads are called thermal overloads. They can be drawn as an inverted disk or as a set of hooks. The inverted disk represents a bimetal disk that warps when it heats up. Bimetal overloads are a very common type of thermal overload. Inline thermal overloads can be drawn as a set of normally closed points after the hooks, just the hooks by themselves, or the inverted disk. Magnetic overloads use the same symbol commonly used for solenoid coils. Pilot-duty overload relays use either the hooks or

Figure 38-28 Overload symbols: bimetal overload, internal overload, thermal in-line overload, thermal overload relay, magnetic overload relay.

diagonal to represent the coil and a separate set of normally closed contacts. Figure 38-28 shows a variety of overload symbols.

38.10 THE LEGEND

Remembering so many different symbols and variations could definitely be a challenge. Fortunately, diagrams come with a legend that identifies which symbols are used and what they represent. Other information such as abbreviations for wire colors and different line styles are also explained. The first place to begin when reading a new diagram is at the legend. It is the instruction manual for the diagram. Most manufacturers use letter designations to identify the components in a diagram. They typically choose letters that make it easier to identify the components without constantly looking back and forth between the legend and the diagram. For example, the letter *c* is often used to represent a compressor contactor. However, technicians should check the legend first rather than assuming they know what the manufacturer intended. For example, one manufacturer uses the abbreviation *IBM* to represent an induced draft blower motor while another uses the same three letters to represent an indoor blower motor. Some manufacturers use the letter *M* and a number for all motors and the letter *K* and a number for all relays and contactors. You have to look at the legend to determine which relay is represented by *K1*. Figure 38-29 shows a schematic and connection diagram with a typical diagram legend.

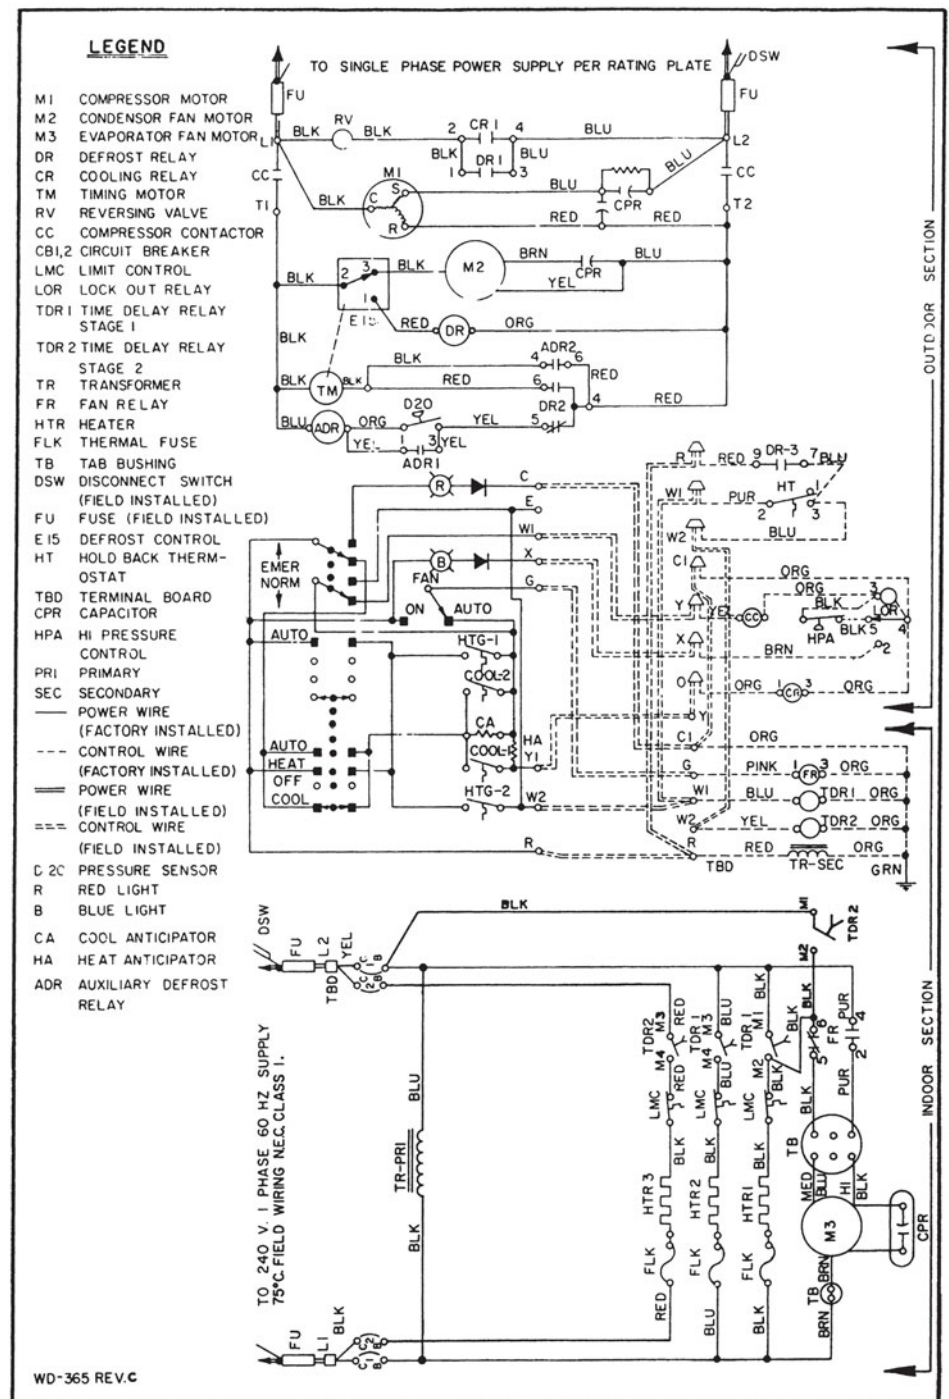

Figure 38-27 Pilot-duty overload.

Figure 38-29 The legend on the left identifies the symbols used in the diagram.

38.11 TYPES OF DIAGRAMS

All diagrams do not serve the same purpose. Diagrams are used to show the logic of the electrical circuits, the location of electrical components, the terminal designations on the components, the routing of the actual wires on the unit, the colors and/or labels of the wires used, where the field power wiring for the unit should be connected, and where the field control wiring needs to be connected. Each diagram typically contains more than one type of information, but no single diagram will convey all this information. Manufacturers use multiple diagrams to accomplish this.

Common types of diagrams used in HVACR include the following:

- Ladder diagram
- Schematic diagram
- Component location diagram
- Point-to-point diagram
- Pictorial diagram
- Label diagram
- Factual diagram
- Field connection diagram
- Installation diagram

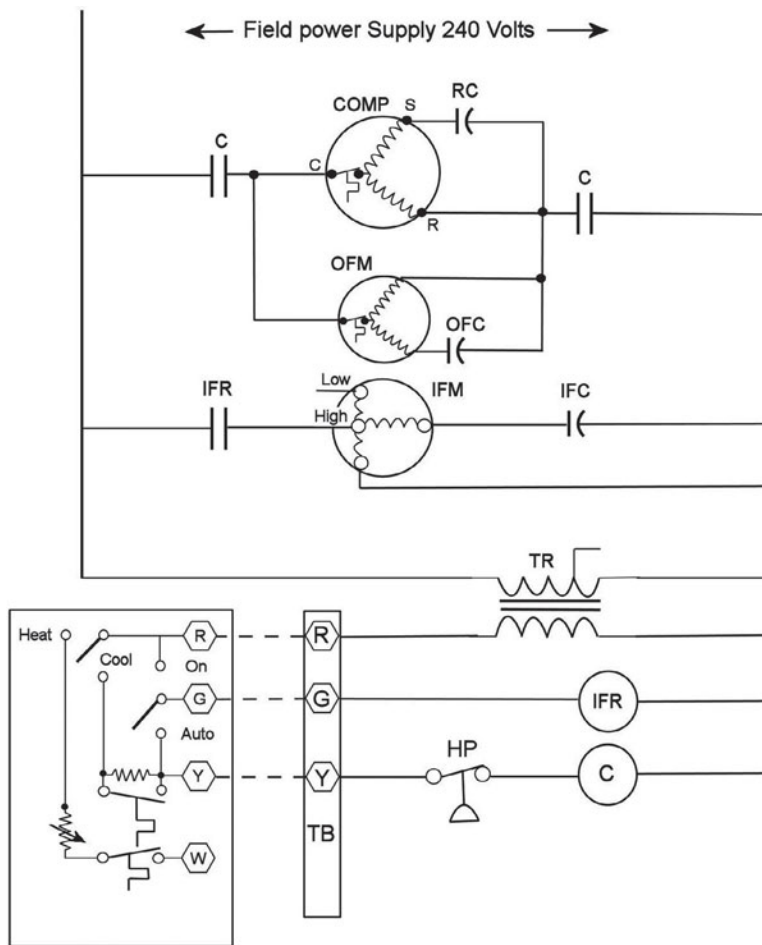

Figure 38-30 Ladder diagram.

38.12 LADDER DIAGRAMS

A ladder diagram is a symbolic representation of circuit logic. Line voltage is represented as rails on a ladder, and individual circuits are shown as rungs (Figure 38-30). Thus, L1 will run down the left side of the diagram, and L2 down the right side. Each circuit is shown as a line running between the two lines representing L1 and L2. Ladder diagrams do not show the actual wire routing, but show a circuit-by-circuit representation of the electrical system. Symbols are placed according to their electrical function, not according to their actual location in the unit. For example, the parts of a relay or contactor are shown in multiple places on the diagram because the coil is in a different circuit from the contacts. The coil and contacts of the contactor are shown in Figure 38-31. Note that the coil is in the 24 V control section of the diagram and the contacts are in the line-voltage portion. When the coil is energized, it closes its contacts, completing a circuit to the compressor motor. Most ladder diagrams have the power supply at the top and locate the largest line voltage loads near the top of the diagram (see Figure 38-30). Small line voltage loads, such as relay coils and solenoids, are usually drawn further down the ladder. For systems with control transformers, the transformer primary winding is the last line voltage load on the ladder. A new ladder is drawn underneath the transformer secondary winding (see Figure 38-30). Although ladder diagrams usually draw the power lines vertically, they can be made with

the power lines drawn horizontally, looking like a ladder lying on its side (Figure 38-32).

Figure 38-31 Contactor coil and contacts are in different places on the diagram.

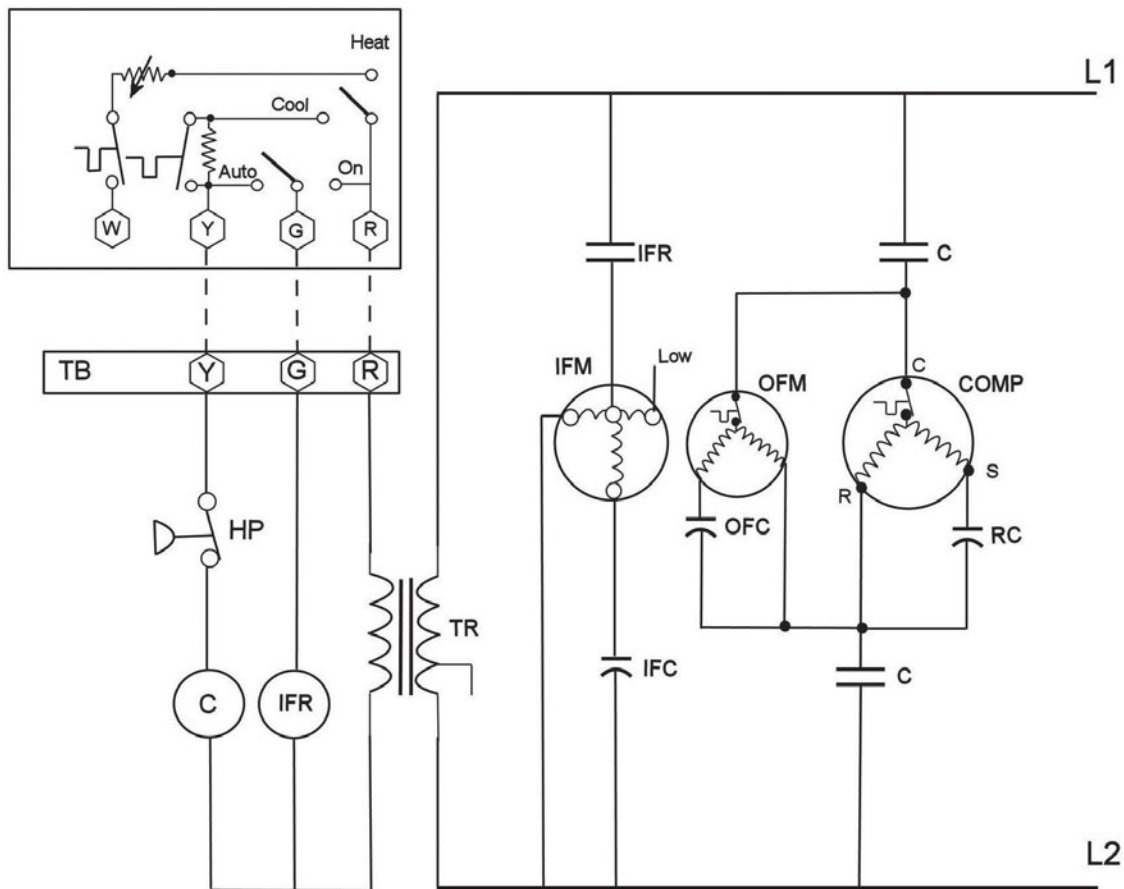

Figure 38-32 Sideways ladder diagram.

SERVICE TIP

Ladder diagrams are very useful for determining the operational sequence of a unit. Technicians can use a ladder diagram to learn how a piece of equipment they have never seen operates.

38.13 SCHEMATIC DIAGRAMS

Schematic diagrams, shown in Figure 38-33, are the most common. They are intended to show the scheme, or logic, of the electrical circuitry. Like ladder diagrams, schematic diagrams do not show the actual wire routing but try to show a circuit-by-circuit representation of the electrical system. Most schematics are at least partial ladder diagrams. However, most manufacturers include some extra information on their schematics. While a pure ladder diagram does not attempt to arrange any of the diagram to represent the physical reality of the unit, schematics commonly have some part of the diagram arranged to represent a part of the unit. For example, many schematics have the thermostat connections or unit terminal board connections drawn in the schematic in the same order and arrangement as in the unit. This allows the schematic to double as a connection diagram, but it breaks the ladder concept because the actual wire connections cannot be shown and keep all the circuits as parallel lines.

Many schematic diagrams vary the style of the lines in the diagram to distinguish between line voltage, low voltage, factory wiring, and field wiring. The heavier lines represent line voltage wires, while the lighter lines represent the low-voltage wires. Solid lines represent factory wiring, and dashed lines represent field wiring. Connections between wires can be represented different ways. In some diagrams, any lines that cross are connected. In these diagrams, when wires cross that are not connected, one line has a half circle loop over the other. Still other diagrams use a small, solid dot where wires connect. Wires that cross without the dot in these diagrams are not connected. Figure 38-34 shows some common line uses.

SERVICE TIP

Wiring diagrams for equipment may change as the manufacturer makes minor modifications to the equipment's components. Because wiring diagrams today are computer generated, it is easy for the manufacturer to make these minor changes without having to redraw the entire diagram. For this reason, many manufacturers' diagrams may be slightly different from one another but look very similar. Make certain that you are using the correct diagram for the piece of equipment you are currently servicing by checking the model number on the diagram with the equipment model number.

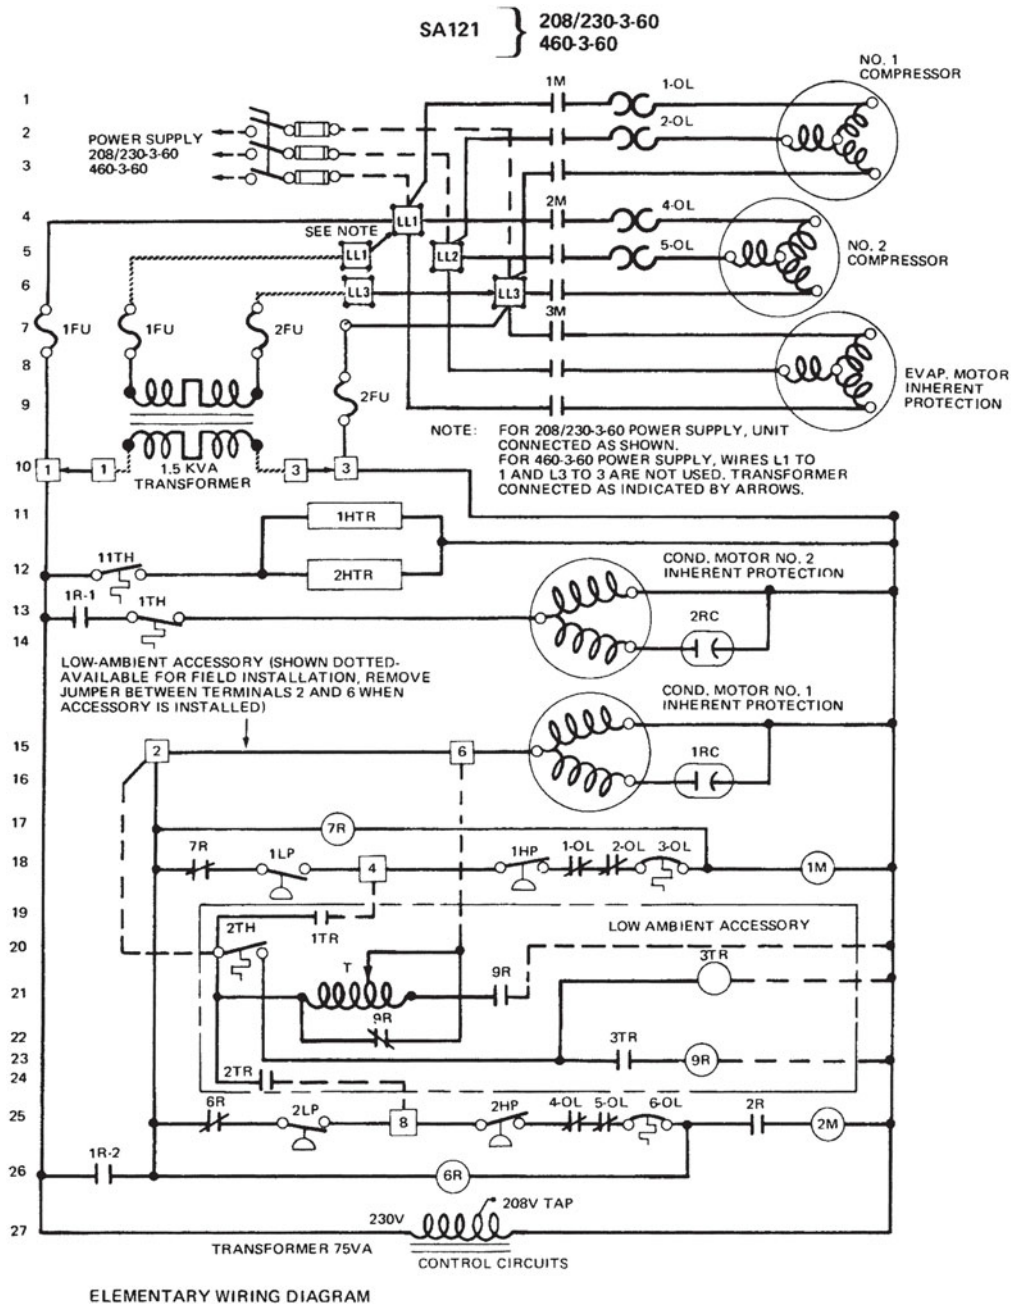

Figure 38-33 Schematic diagram.

Figure 38-34 Line conventions.

38.14 COMPONENT LOCATION DIAGRAMS

A component location diagram shows where each component is located in the unit (Figure 38-35). This is especially helpful when a unit has multiple components that are physically identical. Component location diagrams usually do not show any wiring or circuits. They are often used in conjunction with ladder or schematic diagrams. The schematic diagram shows how the unit operates and field wiring connections; the component location diagram shows where the parts are actually located in the unit.

Figure 38-35 Component location diagram.

38.15 POINT-TO-POINT DIAGRAMS

A point-to-point diagram shows how the wires are routed to and from each connection point on the system. Lines represent actual wires on the system. Typically, point-to-point diagrams also show the wire color and any terminal labels. Components may be arranged on the diagram as they are in the unit, but this is not always the case. Point-to-point diagrams are useful when replacing components because they show where actual wires physically connect to specific component terminals. However, it is very difficult to trace circuits on a point-to-point diagram because the wires cross over each other and represent physical wires rather than circuits.

38.16 PICTORIAL DIAGRAMS

A pictorial diagram, also called a label diagram, combines the component location diagram and the point-to-point diagram. The pictorial diagram looks like a picture of the control panel in the unit with lines representing the actual wires. The components are located on the diagram exactly as they are in the unit, and the lines represent actual physical wires. Pictorial diagrams are great for replacing components and identifying original factory wiring, but they are not very much help in tracing circuits or understanding unit operation. Pictorial or label diagrams are often paired with schematic diagrams. In Figure 38-36, the left side is a pictorial diagram and the right side is a schematic diagram of the same unit.

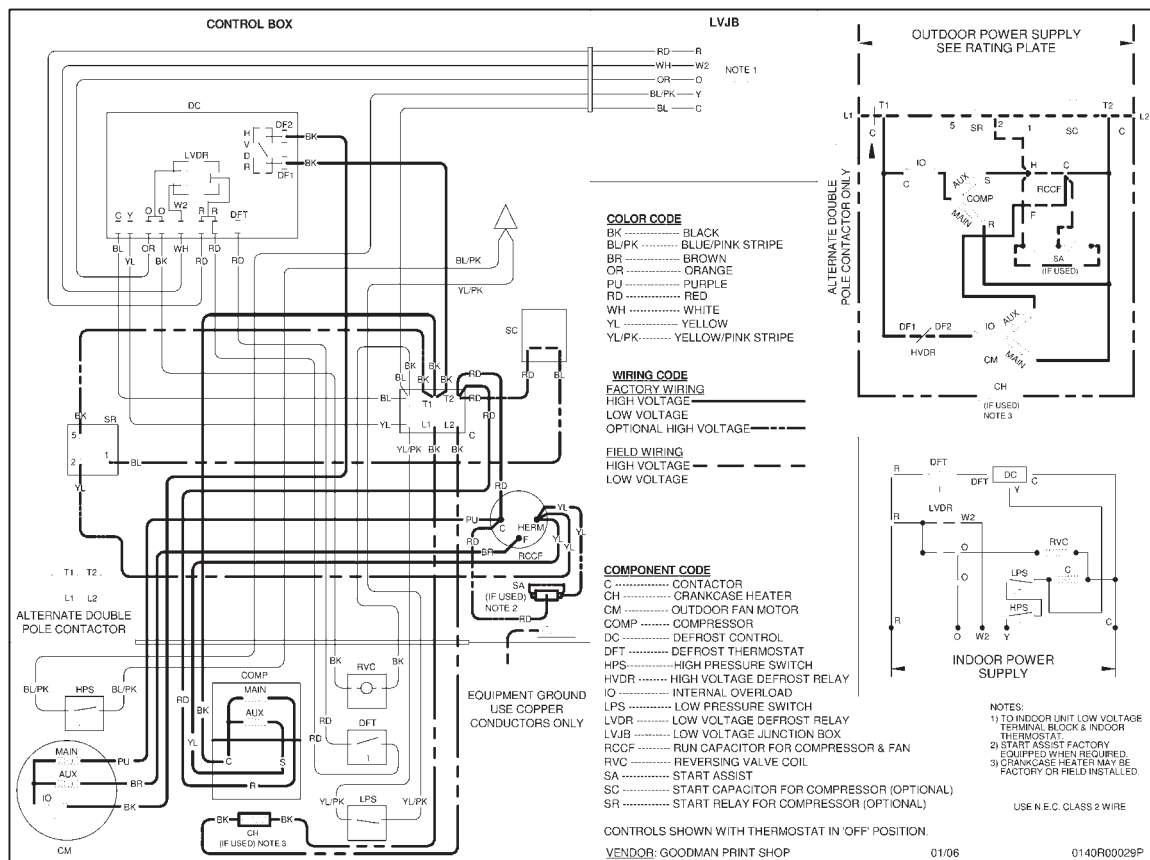

Figure 38-36 Pictorial and schematic together.

SERVICE TIP

Pictorial diagrams are often used in conjunction with ladder or schematic diagrams. The ladder diagram allows the technician to trace circuits and determine the components they want to check, but they don't help locate the actual component and wires that must be checked. Pictorial diagrams can do that. Together they are very powerful.

38.17 FACTUAL DIAGRAMS

A factual diagram is a combination of a ladder diagram and a point-to-point diagram. Factual diagrams are still arranged in a ladder, but references at each connection point show where the actual wires run to and from on the unit.

Figure 38-30 shows a ladder diagram of a packaged air conditioner, and Figure 38-37 shows a factual diagram of the same unit. The parallel lines represent specific physical wires. This often results in multiple parallel lines running between the power rails on the side and a component (Figure 38-37). Component terminals are labeled just as they are on the components. Terminals with names or numbers are shown inside a hexagon—for example, the compressor motor terminals in Figure 38-37. Terminals on components that do not have a number or label are shown as small circles—for example, the transformer connections in Figure 38-37. Wires are identified by their color or number at each connection inside the diagram. References along the side rails identify where each wire is headed. For example, in Figure 38-37, there are two wires connected to the L2 contactor terminal: a red wire and an orange wire. The connection on the side rail indicates that the red wire goes to the IFC (indoor fan capacitor). Down lower on the rail, you see

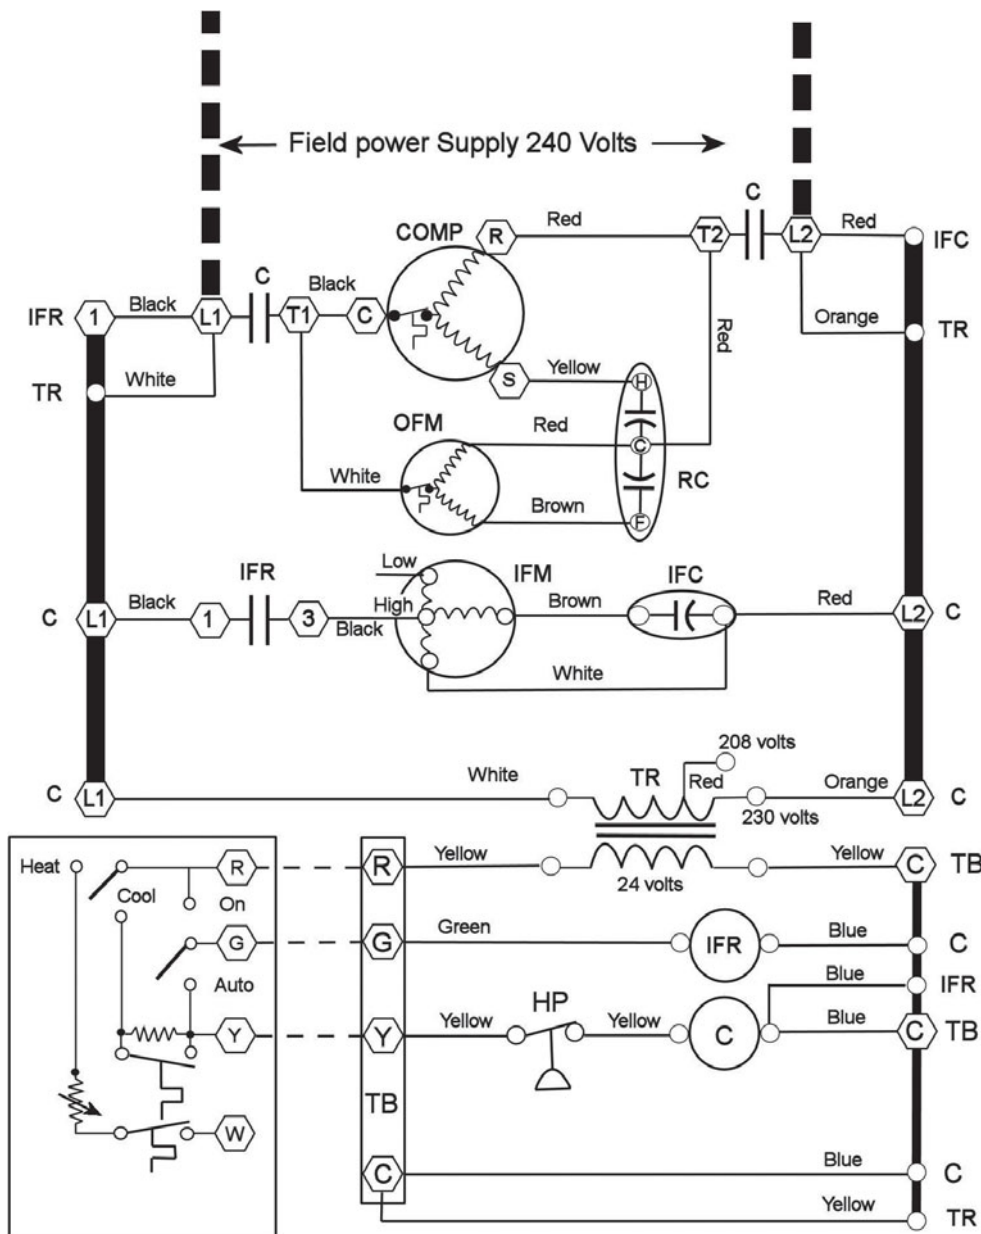

Figure 38-37 Factual diagram.

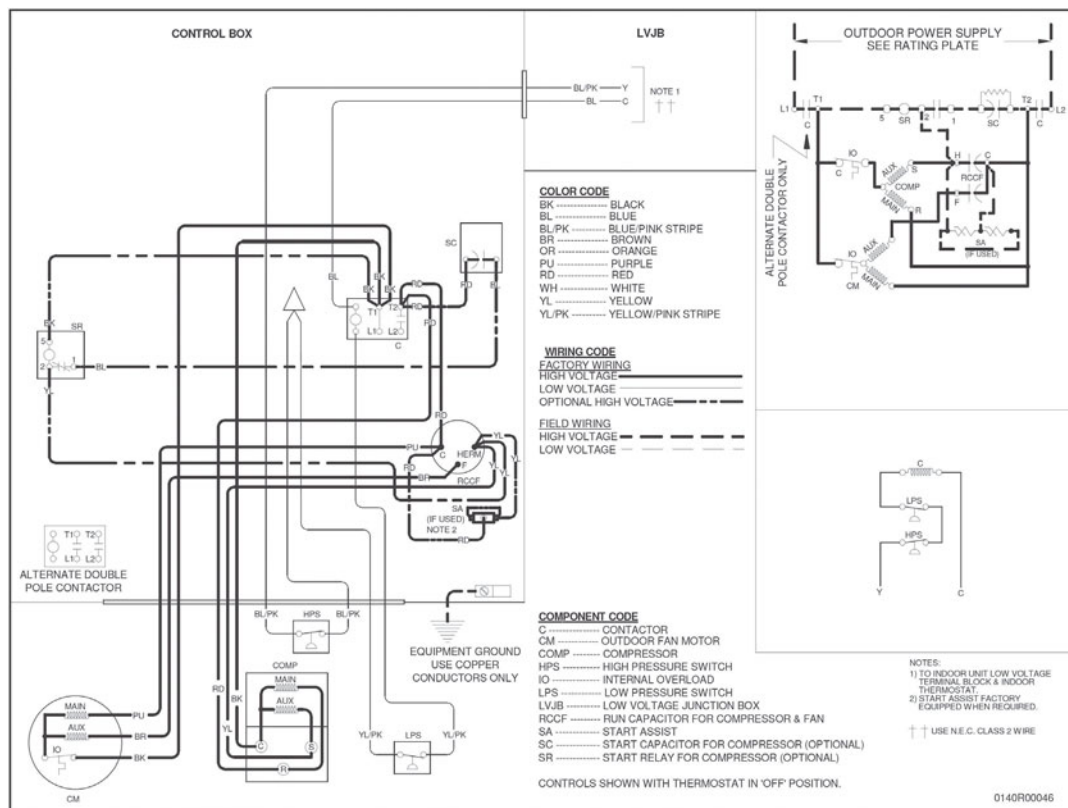

Figure 38-38 The dashed lines on the right show where wires are connected during installation. (Courtesy Goodman Global Group, Inc.)

the L2 contactor terminal. Following the wire at that point, you see a red wire connecting to the IFC. Similarly, the orange wire connects between the contactor L2 terminal and the transformer, as indicated by the terminal designations along the power rail.

38.18 FIELD CONNECTION DIAGRAMS

Field connection diagrams, also called installation diagrams, identify the electrical controls in the control box and indicate the necessary field wiring. Field connections are indicated on the right-hand side of Figure 38-38 using dashed lines. Field connections are frequently shown as dashed lines and shaded areas. The field connection diagram is designed to instruct the installing electrician or technician how to run the proper power supply to the unit and the correct wiring between different sections if the unit consists of more than one section. Internal wiring is not shown since the principal use of the field connection diagram is for installation. It is possible for a diagram to show field connections in addition to other details, as in Figure 38-29.

38.19 BUILDING AN AIR-CONDITIONING SCHEMATIC

One of the best ways to understand the logic of schematic diagrams is to draw them. In this section we build the air-conditioning system diagram shown in Figure 38-39. The diagram will be built circuit by circuit, component by

component, starting with the power supply to the unit, as shown in Figure 38-40. The wires to the disconnect switch are represented by heavy broken lines because they are wired in the field. The power supply shown is single phase, 60 Hz, 230 V current, coming in through wires L1 and L2.

TECH TIP

In some parts of the country, all high-voltage power wiring must be installed by a licensed electrician. In many places, an electrician does the wiring from the breaker panel to the unit disconnect, and the air-conditioning installer wires from the disconnect to the unit. In other locations, air-conditioning installers may do the power wiring from the breaker panel all the way to the air conditioner under certain conditions. Check with your local building inspector to determine the requirements in your area.

Because the compressor is the heaviest load, it is placed in the diagram first, connected to the power supply between L1 and L2. This makes a complete circuit from L1 through the compressor to L2. The compressor will operate when the disconnect switch is closed manually and turn off when the disconnect switch is opened manually. An air conditioner also requires indoor and outdoor fan motors. These are put into the diagram next, as shown in Figure 38-41. The fans are wired in parallel to the compressor and to each other so that all three motors receive full line voltage. All three motors

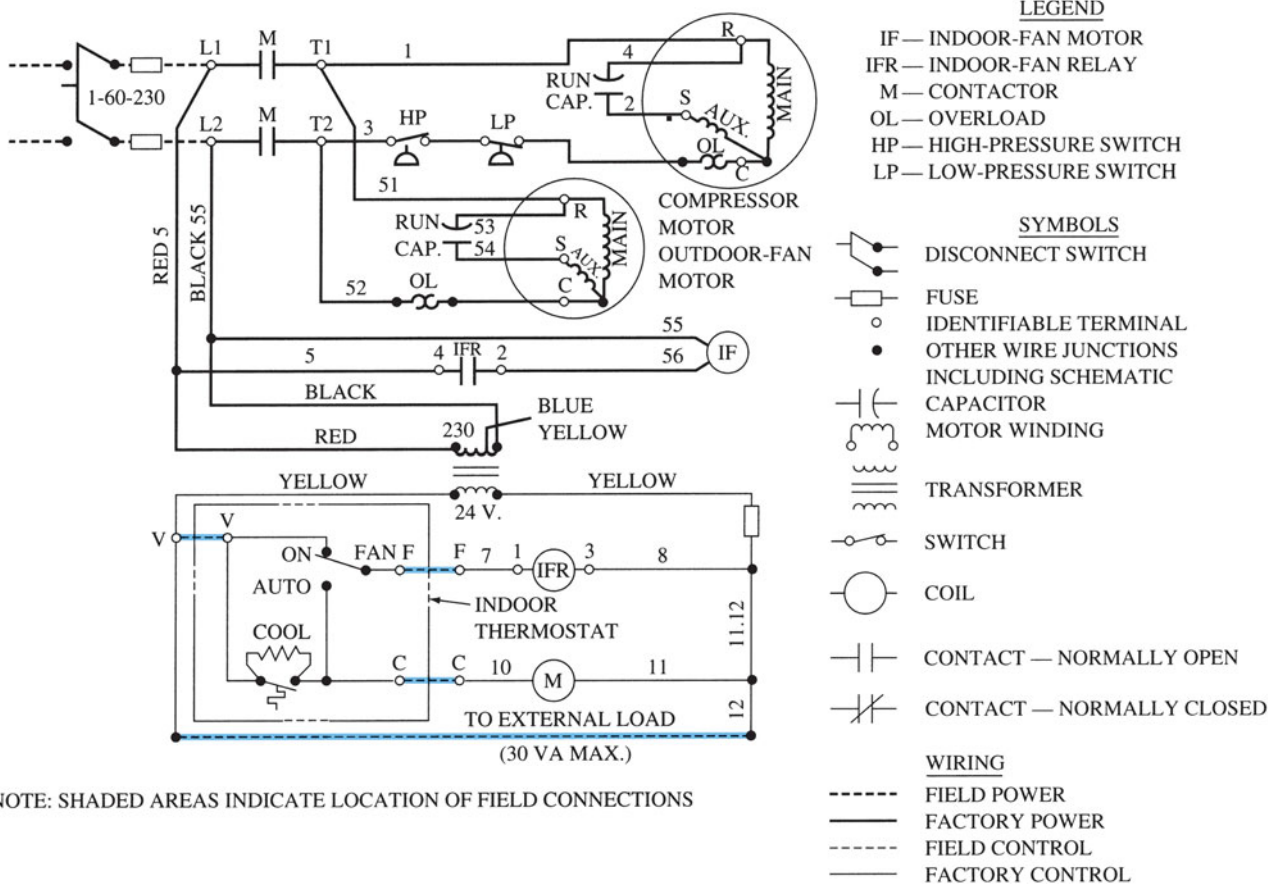

Figure 38-39 Complete wiring diagram for an air-conditioning unit.

are in individual circuits of their own. A path can be traced from L1 to L2 through each motor without going through any other motor. At this point, the system has no controls and does not operate automatically. All three motors will operate whenever the disconnect switch is closed manually. Electrical controls are needed for automatic operation.

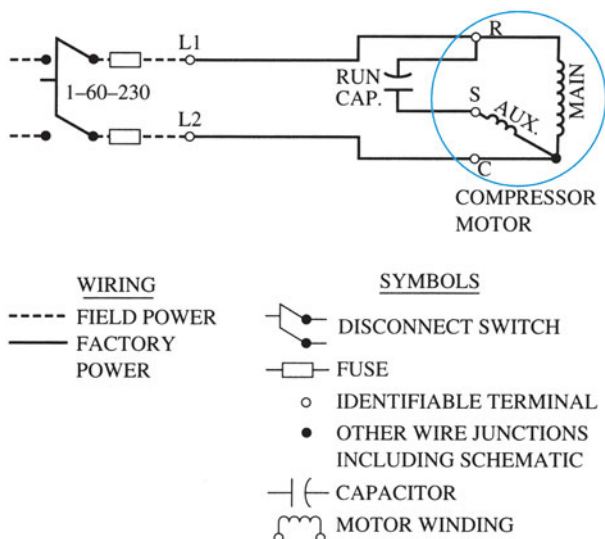

Figure 38-40 Diagram showing the wiring from the disconnect to the compressor motor.

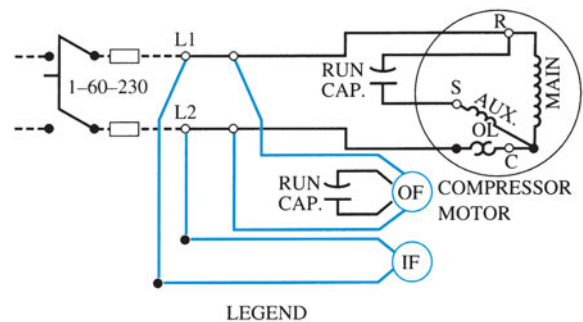

Figure 38-41 Wiring diagram showing the addition of the outside and inside fan motors.

Figure 38-42 Unit operation can be controlled by adding a line-voltage thermostat.

One way of providing automatic operation would be to put a thermostat in series with L1 or L2, (Figure 38-42). This is how window units operate. One disadvantage of using line voltage controls is that switching high current from large loads requires larger components. Line voltage thermostats are fine for window units, but larger systems require heavier switching. Relays and contactors provide a way to switch a high voltage and current with a low voltage and current. Relays and contactors are essentially electrically operated switches.

We will add a 24 V control system consisting of a low-voltage thermostat, a relay, and a contactor to control the motors. The low-voltage source is a small step-down transformer, shown in the wiring diagram in Figure 38-43. The function of the transformer is to reduce the 240 V to 24 V to provide control voltage.

TECH TIP

There are several reasons that most HVACR equipment uses 24 V as the control voltage. First, under most state and local guidelines an electrician’s license is not required to install and service these low-voltage wires. Second, most codes do not require that these connections be made at electrical junction boxes. And third, under OSHA regulations, circuits that have less than 80 V fall under less stringent safety requirements.

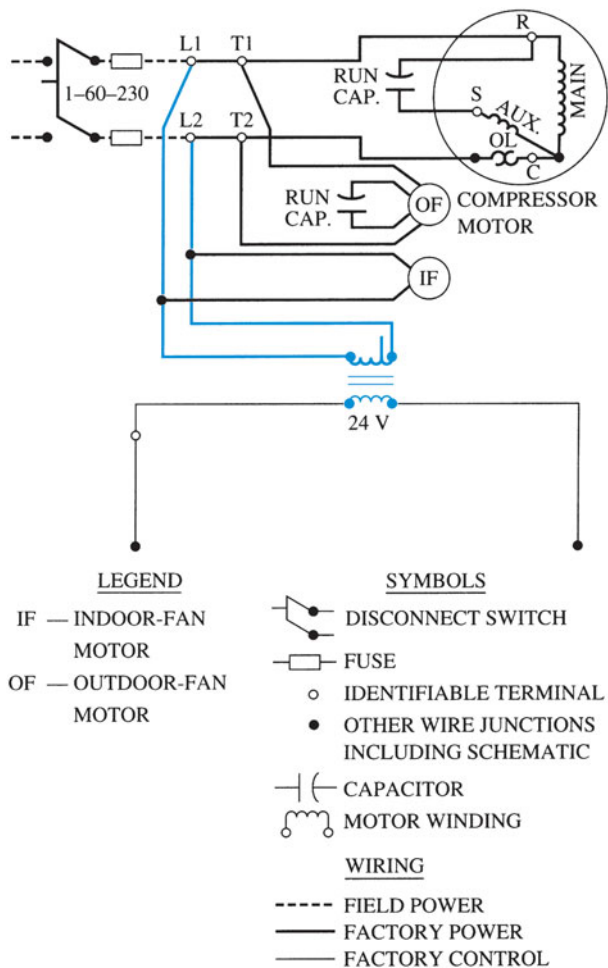

Figure 38-43 Wiring diagram showing the addition of a low-voltage control transformer.

The thermostat controls system operation by taking the 24 V from the transformer and sending it to the fan relay coil and the contactor coil. Terminal R on the thermostat is connected to one side of the low-voltage supply, as shown in Figure 38-44, but nothing will happen until a circuit is completed to the other side of the 24 V supply.

A contactor is added to control the compressor motor automatically. The contactor can be described as an oversized relay with a switch large enough to carry the heavy current drawn by the compressor and a magnetic coil strong enough to actuate the larger switches. The thermostat is wired in series with the contactor coil M (Figure 38-45). This allows it to control the operation of the contactor coil. The contactor coil M will control the M contacts, and the contacts will control the compressor. The contactor contacts must be connected in the power circuit so that they control both the compressor motor and outdoor fan motor. The indoor fan motor must be able to operate independently. Note that the contactor coil and both contactor contacts are marked M for identification. This means that coil M actuates the two contacts marked M. Since both contacts are normally open, they will close when the coil is energized and open when it is de-energized. Another relay is needed to control the indoor fan motor, IF. A fan relay

has been added in Figure 38-46. It has a coil and a normally open set of contacts, both marked IFR. Note that the coil is wired in series with the fan switch in the thermostat, and its contacts are wired in series with the indoor fan motor.

Figure 38-47 shows the completed diagram with the unit operating in cooling. On a call for cooling, current flows through the thermostat to both the contactor coil M and the indoor fan relay coil IFR at the same time. This closes both contacts marked M in the power circuit to the compressor and outdoor fan motors, as well as the contacts marked IFR in the power circuit to the indoor fan motor. The compressor and outdoor fan motors are energized and started through the M contacts. At the same time, the indoor fan motor is also started through closed IFR contacts. The en-

tire system is now energized, and all motors are running automatically.

When the thermostat is satisfied, the cooling thermostat opens the circuit to both the contactor and indoor fan relay coils, their contacts return to their normally open positions, and all motors stop—compressor, outdoor fan motor, and indoor fan motor.

Safety controls can be added to protect the system. In Figure 38-48, overloads have been added to protect the compressor and outdoor fan motor windings against excessive current and temperature. Overloads may be installed inside the motor housing, as shown for the compressor motor, or externally, as shown for the outdoor fan motor.

A high-pressure switch and a low-pressure switch have been wired in series with the compressor motor. They will prevent the compressor from operating under abnormal conditions such as excessive discharge pressure or low suction pressure. The high-pressure switch is actuated by system discharge pressure to open and stop the compressor if the discharge pressure exceeds the switch setting. The low-pressure switch is actuated by system suction pressure to open and stop the compressor if the suction pressure falls below the switch setting. A fuse has been installed in series with the transformer secondary winding to protect the transformer and low-voltage control circuit wiring against excessive current in the low-voltage control system.

For closer control of air temperature in the conditioned space, an anticipator has been wired across the terminals of the thermostat cooling switch. It is a fixed, nonadjustable resistor. When the cooling thermostat opens, a new circuit is made with the anticipator in series with the M coil. In a series circuit, the device with the highest resistance uses most of the voltage. The anticipator resistance is several thousand ohms, much higher than the resistance of the contactor coil, so the anticipator uses virtually all the 24 V, and the contactor turns off even though it is still in the circuit. Heat from the anticipator fools the cooling thermostat into closing early, starting the system before the house temperature has risen above the set point. This gives the system the lead time it needs to start delivering cool air.

38.20 SEQUENCE OF OPERATION

Ladder diagrams are used to determine a system's sequence of operation. The sequence of operation is the order, or sequence, in which electrical loads operate and the conditions that will start or stop each load. To determine a unit's sequence of operation, start by identifying any circuits in the line voltage portion that have a complete path from L1 to L2 when power is applied to the unit. In Figure 38-49, the only circuit that is complete when the power is first applied is the circuit to the transformer primary. All the other line voltage circuits have open contacts or switches in the circuit. The transformer will supply 240 volts to the low-voltage controls when the unit is first energized. Next, identify any circuits in the low-voltage portion that have a complete path. In the top portion of Figure 38-49, there are no low-voltage circuits with a complete path. Some of the switches in the thermostat must change position to energize any of the low-voltage control circuits. In most residential control systems, one side of 24 V power goes to the thermostat and the other side of

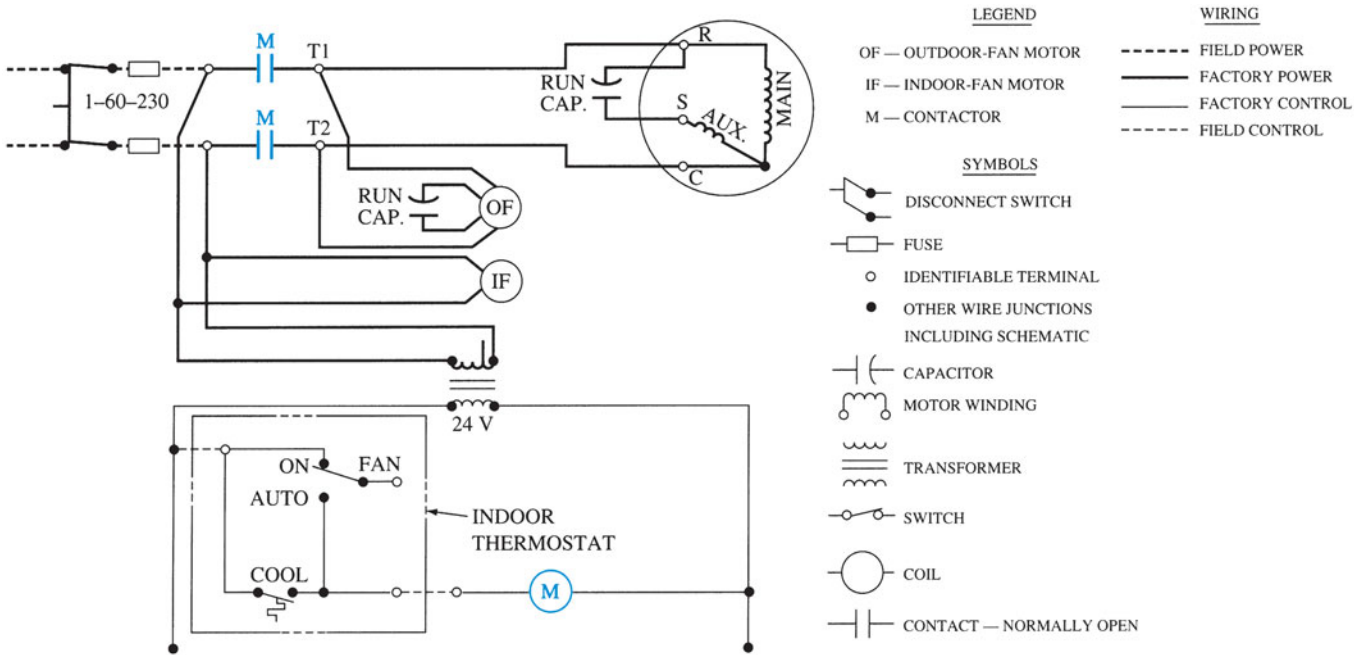

Figure 38-45 Wiring diagram showing the addition of the compressor contactor coil placed in the cooling circuit.

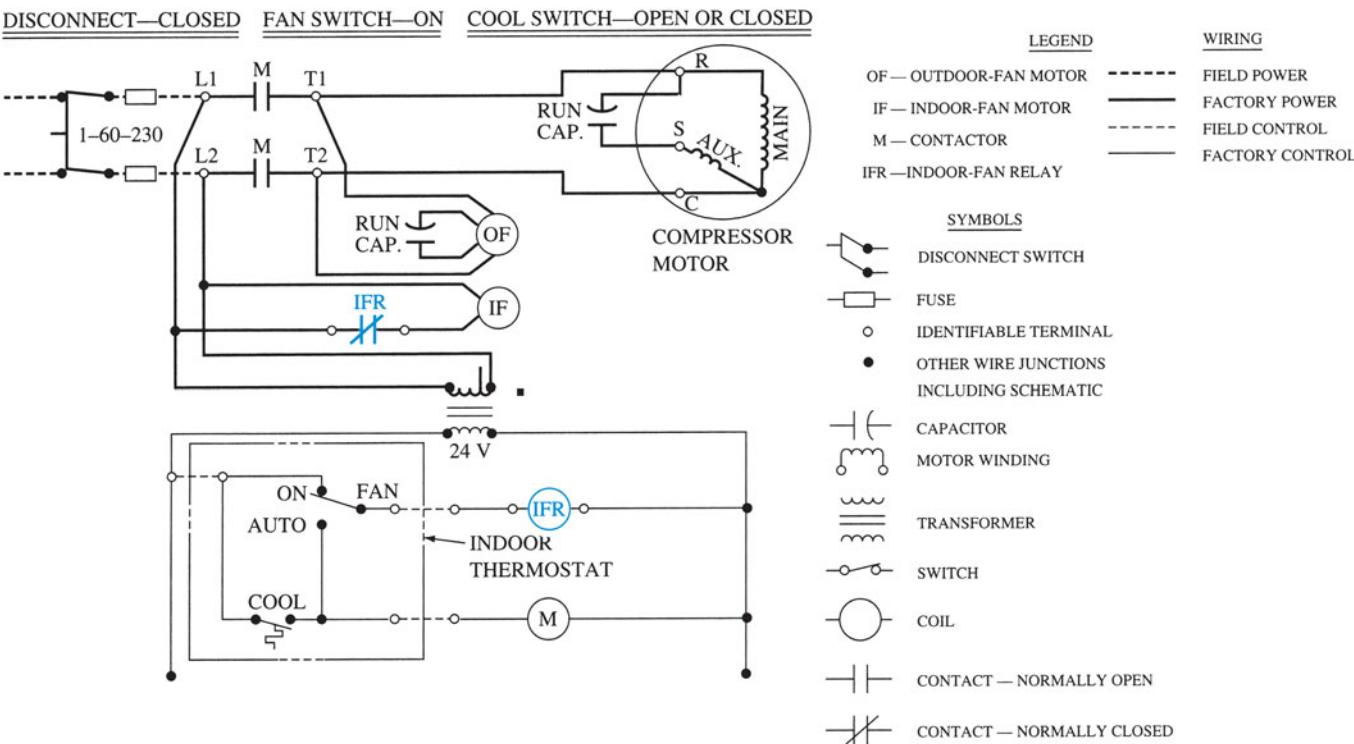

Figure 38-46 Wiring diagram showing the addition of the fan relay operated by the FAN ON switch.

24 V power goes directly to all the low-voltage controls. The thermostat acts like a switch, controlling unit operation by controlling 24 V power to the different low-voltage controls. Most thermostats have two main manual switches: a fan switch with ON and AUTO positions and a system switch with HEAT, OFF, and COOL. The fan switch controls the indoor

fan operation. In the ON position, the fan will operate continuously. In the AUTO position, the fan is controlled by the cooling thermostat. When the thermostat calls for cooling, the fan will operate; when the thermostat does not call for cooling, the fan stops. The system switch controls whether the system operates in heating or cooling or is off.

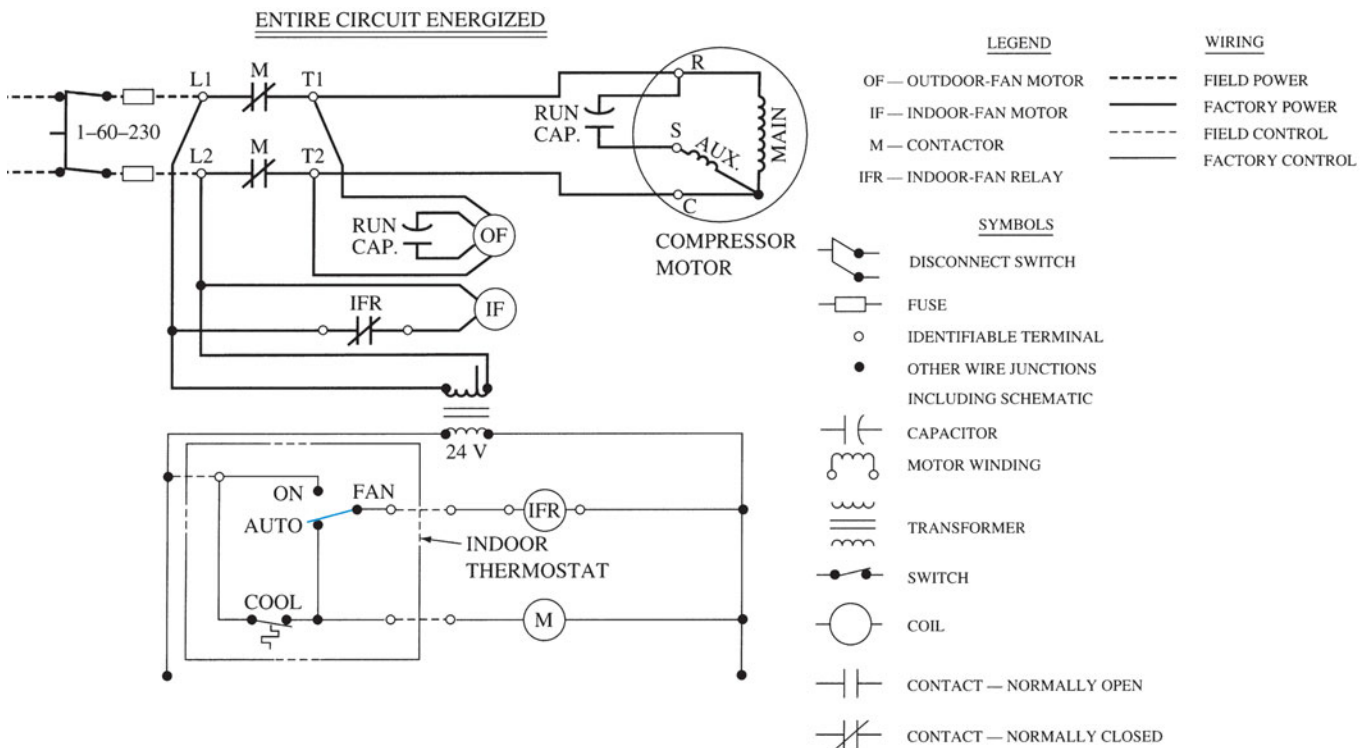

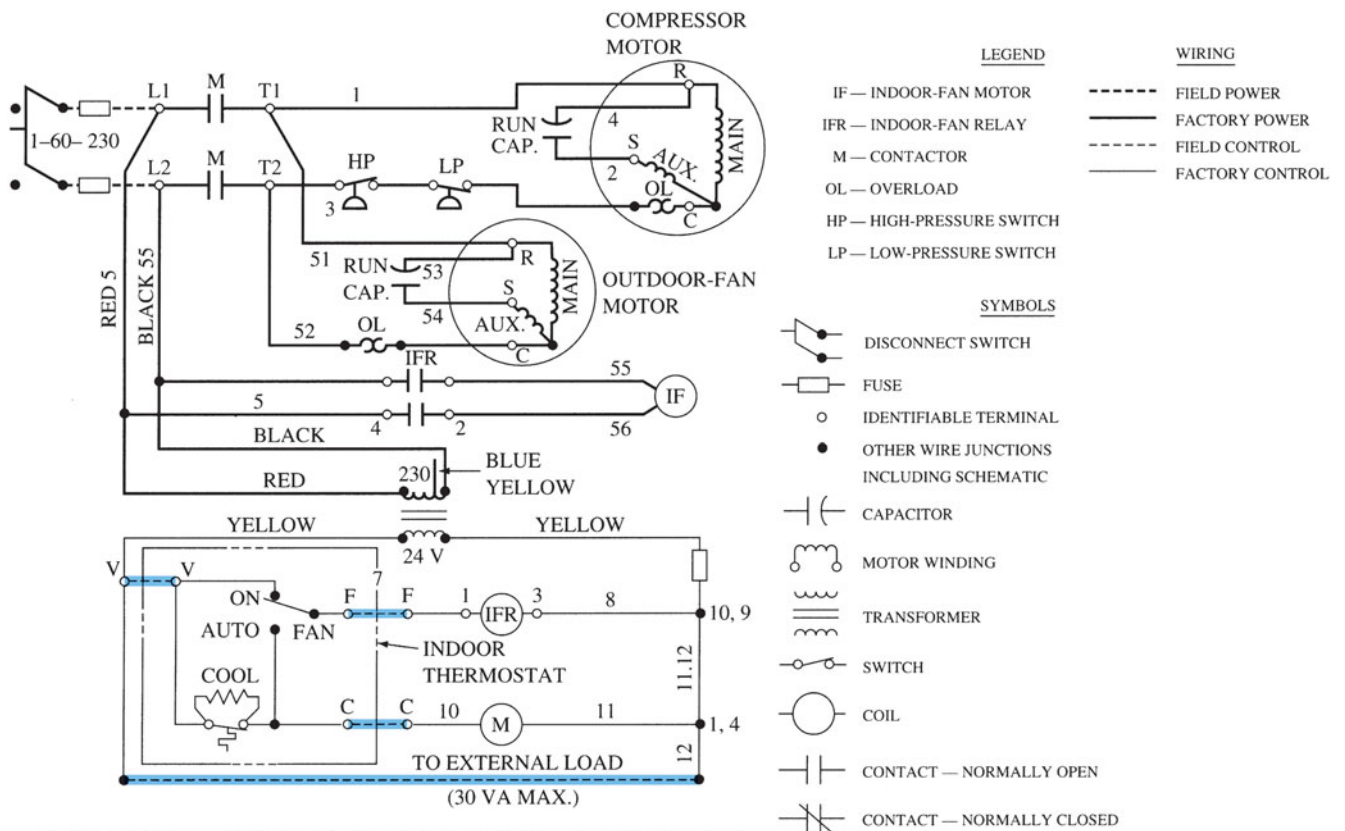

Figure 38-47 Wiring diagram showing fan in AUTO position and thermostat calling for cooling.

NOTE: SHADED AREAS INDICATE LOCATION OF FIELD CONNECTIONS

Figure 38-48 Complete ladder diagram for the air-conditioning unit.

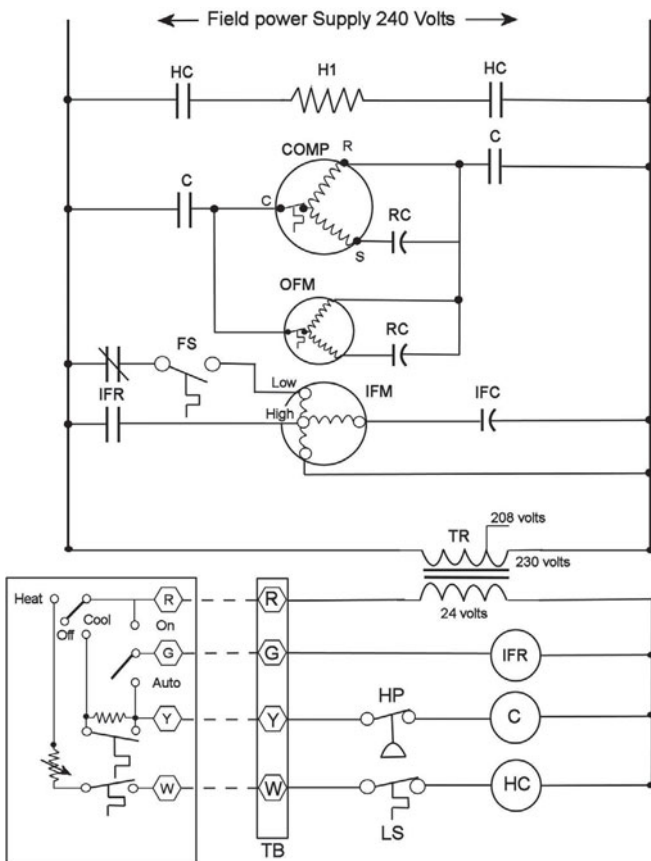

Figure 38-49 Ladder schematic of heating/cooling system.

Cooling Operation

With the system switch in the COOL position and the fan switch in the AUTO position, the cooling thermostat will control unit operation. A temperature rise will cause the cooling thermostat to close, completing circuits to both the indoor fan fan relay (IFR) and the contactor (C) (Figure 38-50). The IFR

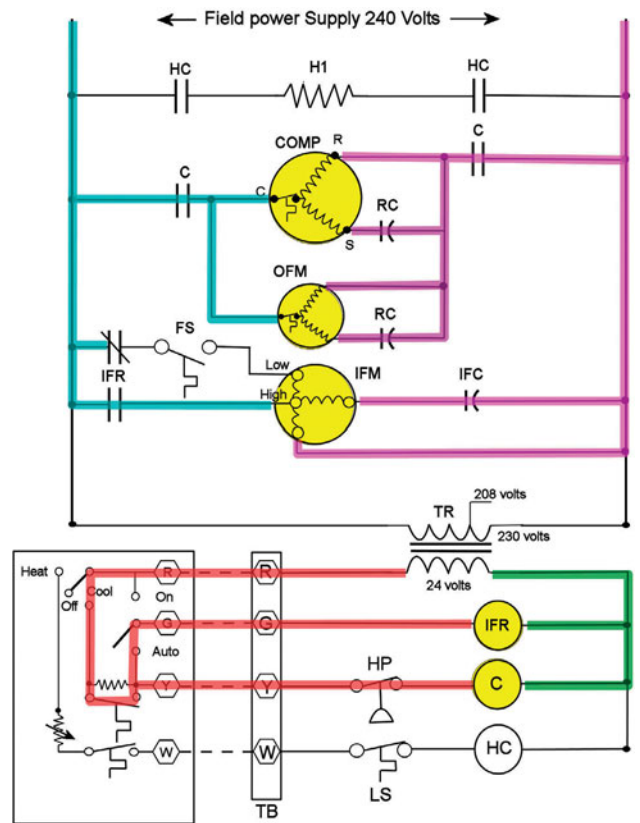

Figure 38-51 IFR and C contacts energizing compressor, outdoor fan, and indoor fan.

coil will close the normally open contacts labeled IFR in the line voltage section, completing a path to the high speed of the indoor fan motor (IFM). The normally closed IFR contacts open, ensuring that the low-speed motor winding cannot be energized. At the same time, the C coil will close the normally open contacts labeled C, energizing both the compressor motor (COMP) and the outdoor fan motor (OFM) (Figure 38-51).

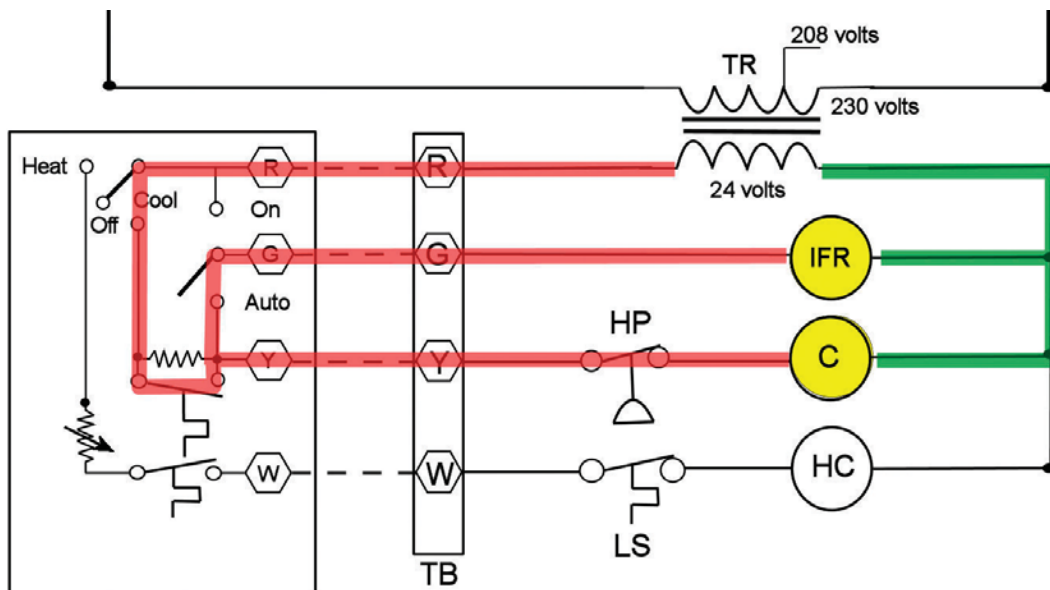

Figure 38-50 Cooling thermostat closing energizing IFR and C.

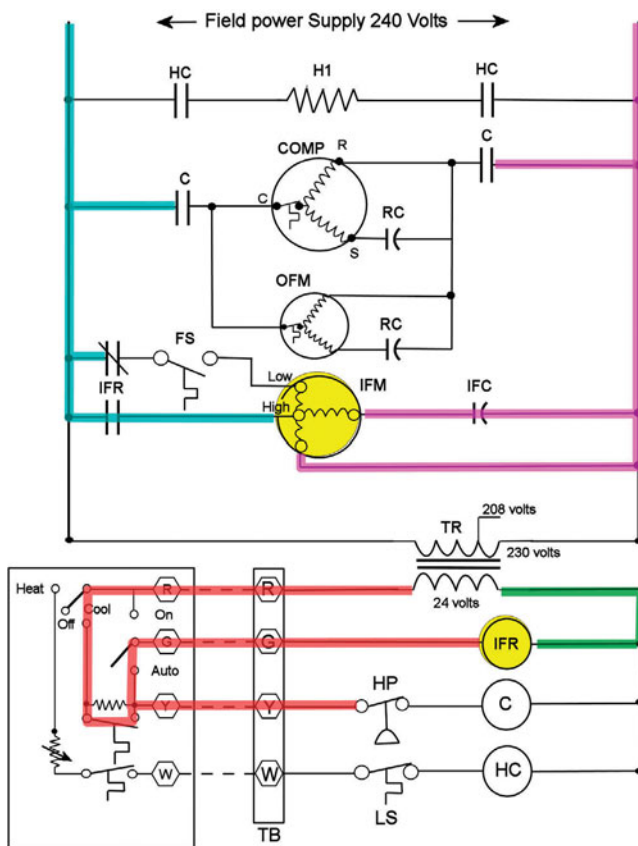

Figure 38-52 HP opening turning off compressor.

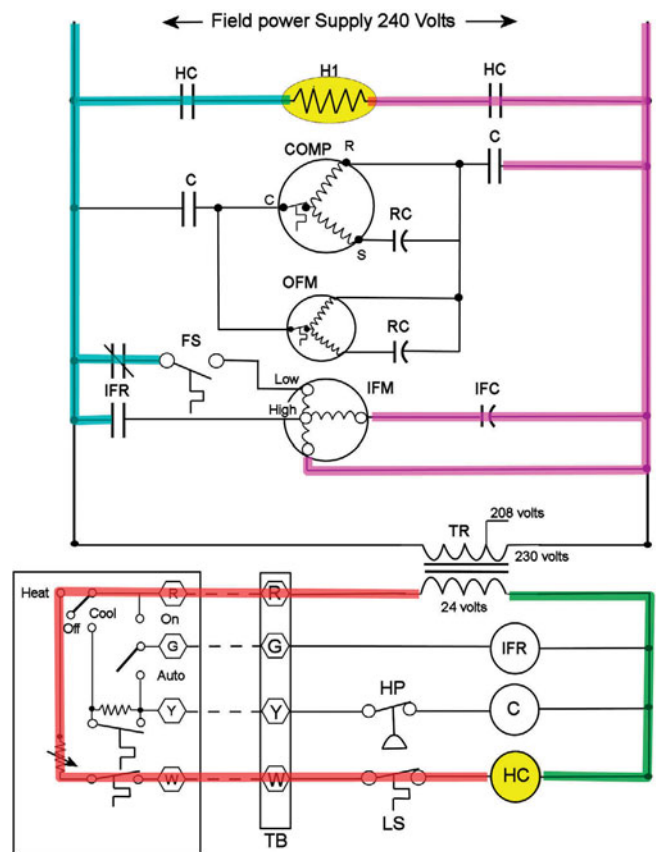

Figure 38-53 Heat strips energized.

If the system pressure rises above a safe operating level, the rise in pressure will open the high-pressure switch (HP). Opening HP will break the circuit to the contactor coil (C), de-energizing it. When the C coil is de-energized, it will open the C contacts in the line voltage section to de-energize the circuits to both the COMP and the OFM (Figure 38-52).

Heating Operation

With the system switch in the HEAT position and the fan switch in the AUTO position, the heating thermostat will control unit operation. A temperature fall will cause the heating thermostat to close, completing a circuit to the heating contactor (HC). The HC coil will close the normally open contacts labeled HC, energizing the electric heater (H1) (Figure 38-53). The fan switch (FS) will close on the rise in temperature created by the heater. The closing of the FS creates a complete circuit through the normally closed IFR contacts to energize the low speed of the IFM (Figure 38-54).

If the heater temperature rises above a safe operating level, the rise in temperature will open the limit switch (LS). Opening LS will break the circuit to the HC, de-energizing it. When the HC coil is de-energized, it will open the HC contacts in the line voltage section to break the circuit to the H1 (Figure 38-55).

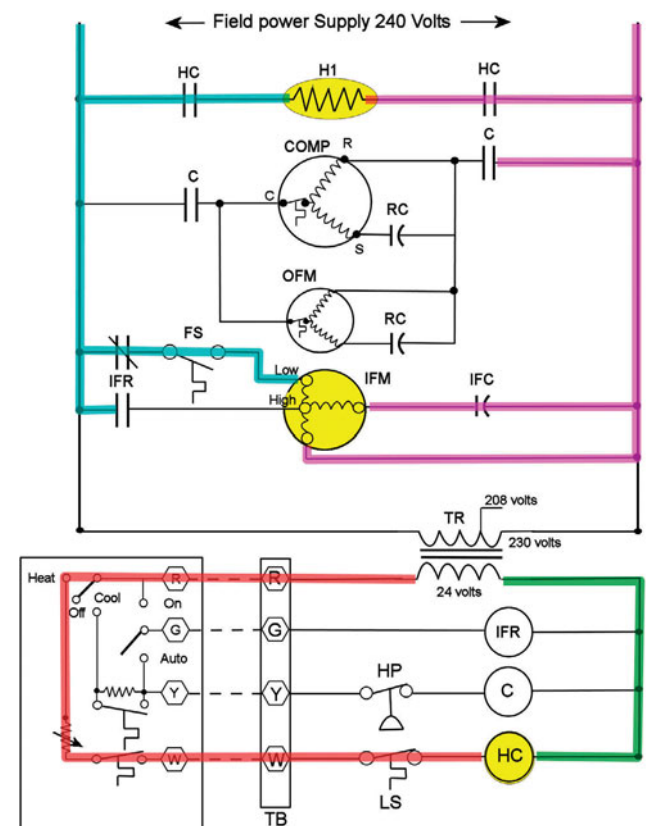

Figure 38-54 Fan switch closing to operate fan in heat.

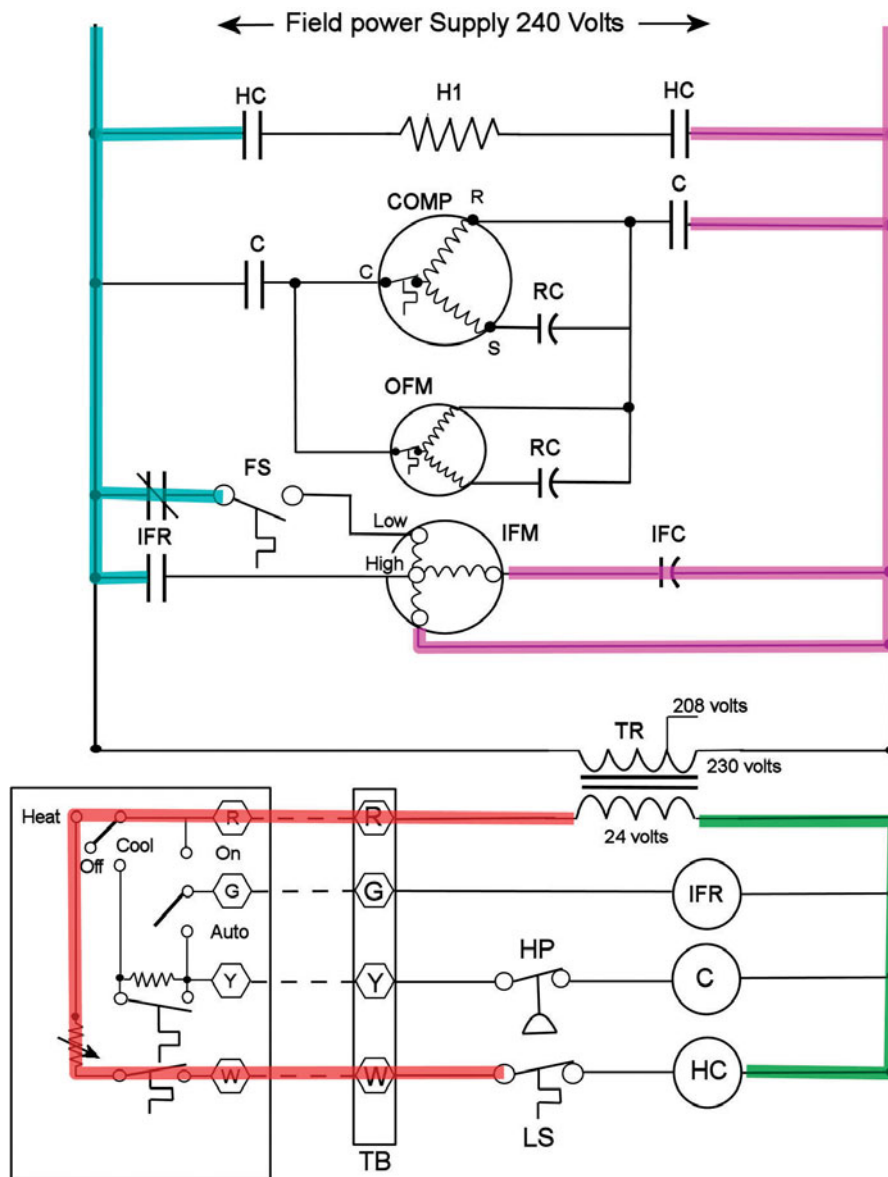

Figure 38-55 Limit switch open to shut off HC; shutting off heater.

UNIT 38—SUMMARY

Reading and interpreting electrical diagrams is absolutely essential to success in the HVACR industry. There are several different types of diagrams. Each provides technicians with different types of information, such as the location of electrical components, the terminal designations on the components, the routing of the actual wires on the unit, the colors and/or labels of the wires used, where the field power wiring for the unit should be connected, and where the field control wiring needs to be connected. Most important, ladder and schematic diagrams show the individual circuits and how the unit operates. Common diagram types include ladder, schematic, point-to-point, pictorial, label, component location, factual, field connection, and installation diagrams. Graphical symbols are used to represent

the electrical properties of standard electrical components. Some components wire into a single circuit and can be represented by a single symbol, such as a pressure switch. Other components are wired in more than one circuit and are represented by several symbols, such as a relay. Different manufacturers often use different symbols for the same components. The diagram legend identifies the symbols used in any particular diagram.

UNIT 38—REVIEW QUESTIONS

1. List the different types of electrical diagrams used by HVACR manufacturers.
2. Which diagram types are most useful for understanding the operation of the unit?

3. Describe the concept behind ladder diagrams.
4. What information does a point-to-point diagram give the technician?
5. What is the difference between a load and a control?
6. What other diagrams are similar to point-to-point diagrams?
7. Why are relay coils and contacts not shown in the same place on a schematic diagram?
8. What information does a factual diagram give that a ladder diagram does not give?
9. How is field wiring distinguished from factory wiring on most diagrams?
10. How is line voltage wiring distinguished from low-voltage wiring on some diagrams?
11. What is a system's sequence of operation?
12. Which types of diagrams are best for determining a system's sequence of operation?
13. Why do many manufacturers provide both schematic and pictorial wiring diagrams on their equipment?
14. What is the purpose of a component location diagram?
15. Why do most manufacturers supply more than one type of diagram with their equipment?
16. Draw symbols for the following switches:
 - a. Close-on-rise thermostat
 - b. Open-on-rise thermostat
 - c. Close-on-rise pressure switch
 - d. Open-on-rise pressure switch
17. What are the two manual switches found on most thermostats?
18. Why are schematic diagrams often not true ladder diagrams?
19. Draw the symbols that are used to represent a(n):
 - a. Relay or contactor coil
 - b. Normally closed relay contacts
 - c. Normally open relay contacts
20. Draw the symbol for a(n):
 - a. Thermal overload relay coil
 - b. Magnetic overload relay coil
 - c. Overload relay contacts
 - d. In-line thermal overload
 - e. Bimetal thermal overload
 - f. Fuse
21. Draw the symbol for a:
 - a. Transformer
 - b. Capacitor
 - c. Red light
 - d. Heater
 - e. Solenoid coil
22. Draw the symbol for a:
 - a. Shaded pole motor
 - b. Single-phase compressor motor
 - c. Three-phase motor
23. In Figure 38-37, what color wire is connected to the compressor start terminal S?
24. In Figure 38-37, how does the HP switch protect the compressor?
25. In Figure 38-37, what is the purpose of the red wire on the transformer primary?
26. In Figure 38-37, what type of device is the IFC?
27. In Figure 38-37, where is line voltage connected to the unit?
28. In Figure 38-37, what controls the outdoor fan motor (OFM)?
29. In Figure 38-48, what does the M coil control?
30. In Figure 38-48, what type of motor is the indoor fan motor (IFM)?

UNIT 39

Control Systems

OBJECTIVES

After completing this unit, you will be able to:

1. explain the purpose of a control system.
2. list the different types of control systems.
3. explain the difference between open and closed loop control systems.
4. identify standard terminal designations in residential HVACR control systems.
5. use schematic diagrams to describe the operating sequence of standard HVACR equipment.

39.1 INTRODUCTION

The control system is the HVACR nervous system. Like a nervous system, the control system regulates the operation of all the major components to ensure that they function properly together. Effective system troubleshooting requires a thorough understanding of the operation of the control system. Technicians must understand control systems to truly understand HVACR equipment operation. This unit will discuss the major types of control systems and then look at some specific residential relay control systems. Communicating control systems are covered in Unit 40, Communicating Control Systems, and commercial control systems will be discussed further in Unit 78, Commercial Control Systems.

39.2 CONTROL SYSTEM FUNDAMENTALS

An HVACR control system regulates the operation of HVACR equipment in response to a monitored condition, such as temperature, pressure, or humidity. At its most basic, a control requires a sensor to monitor a condition, an actuator to cause a change based on what is sensed, and a means of linkage or communication between the sensor and actuator. These elements can be separate devices, or they can all be incorporated into a single device. A room-temperature sensor and an electronic controller connected together by wires in an electronic control system would be an example of multiple devices performing together as a single control. A typical low-voltage wall thermostat would be an example of a control in a single device (Figure 39-1). A control system can consist of a single control, or it can incorporate several controls, operating equipment based on several monitored conditions.

Controls and control systems can be described as either open or closed loop. An open-loop control system does not affect the condition it is sensing. A control that regulates the operation of a piece of equipment based on the outdoor temperature is an open loop since the system cannot control the outdoor temperature. An outdoor thermostat on a heat pump system that will only let the auxiliary heat energize below a particular outdoor temperature is an

Figure 39-1 Low-voltage thermostat.

example of an open-loop control because the system is not controlling the outdoor temperature (Figure 39-2).

A closed-loop control system controls the condition that it is sensing (Figure 39-3). This allows the control to regulate a condition based on the results achieved. Connecting the output back to the input is called feedback. A room thermostat that controls the operation of a heating system based on the room temperature is an example of a closed-loop system because it is controlling the temperature it is sensing. The change in room temperature provides feedback to the thermostat.

Control systems generally control unit operation to maintain a desired condition by one of two methods: two-position control or modulating control. Two-position controls cycle system components on and off, much like a toggle switch. You either have all the light or no light at all. Modulating controls provide levels between on and off; much like a light dimmer controls the light output for

Figure 39-2 Outdoor thermostat.

Figure 39-3 A closed-loop control system uses feedback.

light levels between full light and no light. A modulating control varies the amount of conditioning produced to match the need.

39.3 TYPES OF CONTROL SYSTEMS

Control systems can be grouped by their power source and their general operating principle as electromechanical, pneumatic, electronic, and direct digital (Figure 39-4). Most residential units employ electromechanical control systems. Electromechanical control systems are two-position controls that use mechanical switches and magnetically operated devices. Units respond to the presence or absence of 24 V control power. Relays are typical electromechanical

Figure 39-4 Controls shown clockwise from the left: electromechanical, pneumatic, electronic, direct digital.

Figure 39-5 Control board used in a typical air-conditioning system.

controls. When the relay coil receives 24 V, its contacts close to operate a motor or other controls. Most residential units today have electronic boards, but the presence of a board does not make the control system electronic. Although the boards operate electronically, most of them imitate relay functions. Many actually have small relays built into the board. The board either sends voltage to different controls and loads to operate them or does not send voltage to them to turn them off. Figure 39-5 shows a typical electronic board in a relay-type control system.

TECH TIP

Electromechanical control systems are often referred to as relay control systems because of their reliance on relays to control the operation of motors and system components.

Pneumatic controls operate on air pressure. Pneumatic control systems are modulating systems. The output of a pneumatic control is an air pressure that varies in proportion to the condition being sensed. They can position valves and dampers in any position between fully open and fully closed by controlling the amount of air pressure going to the actuator operating the valve or damper. Pneumatic controls were used for many years in commercial applications, and there are still many operating pneumatic systems, but they are seldom used today in new buildings. Figure 39-6 shows a typical pneumatic valve.

Figure 39-6 Pneumatic water valve.

Electronic controls are also modulating controls. The output of an electronic control system is a variable dc voltage or current that is proportional to the condition being sensed. Figure 39-7 shows a typical dc voltage ramp used in an electronic control system. They can position valves and dampers in any position between fully open and fully closed. Electronic controls have the ability to adjust the feedback to the control to maintain a closer tolerance.

The newest controls are called direct digital controls (DDCs; Figure 39-8). Direct digital controls are control systems that have their own built-in microprocessors. DDC systems are similar to computers: they take input signals, process the signals according to a program, and then provide output. The DDC controllers that connect to motors

Figure 39-7 Voltage ramp for a dc control system.

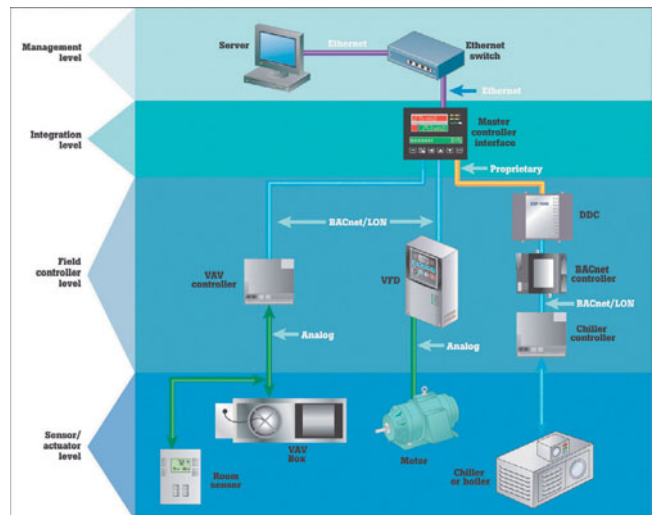

Figure 39-8 DDC control system.

and system sensors typically have both analog and digital input and output. The controllers communicate with each other like a computer network. Information and commands are sent over a network, which allows the components to communicate with each other. DDCs have their own microprocessors, allowing them to respond intelligently to changes. The first DDC systems were exclusively commercial systems. However, there are now many residential communicating systems available in high-end equipment. See Unit 40, Communicating Control Systems, for more information on residential communicating controls. The remainder of this unit concentrates on control systems and diagrams for typical residential relay-type control systems.

39.4 SYSTEM CYCLING

Regardless of the type of control system, the controls must determine when to deliver conditioning to the space and when to stop delivering it. For two-position controls, the resulting on-and-off operation is called cycling. With both two-position and modulating controls, there can be a significant difference between the setpoint and the actual temperature because of equipment and control system characteristics.

The difference between the minimum and maximum room temperatures is called the system swing. Mechanical bimetal thermostats can have a swing as much as 5°F. Proportional control systems usually have less swing than two-position systems. In both cases, the swing is affected by equipment sizing. As a general rule, oversized equipment causes increased cycling and larger swings. Even valves designed for proportional flow have a minimum delivery. If the valve is oversized it will not be able to open to a flow that meets the need. It will either be too open and deliver too much flow or shut off and deliver too little. This is like trying to make a 90° turn into a driveway going 60 miles per hour. You will drive back and forth in front of the driveway but never make the turn. This type of operation is called hunting.

Figure 39-9 Heating and cooling anticipators.

Swing is largely caused by system overshoot and lag. Overshoot describes a condition where the system heats or cools past the setpoint. An example of overshoot is the cool-down cycle in furnaces. Furnace fans typically continue to operate and deliver heat even after the thermostat is satisfied in order to cool the furnace down. If the thermostat does not shut off the call for heat until the room is at the setpoint, the furnace cool-down will heat the room past the setpoint. To avoid overshoot, the call for heat must be terminated before the room reaches setpoint temperature. Mechanical thermostats use heat anticipators to fool the thermostat into shutting off early. A heat anticipator is a small heater with a very low resistance that is wired in series with the heating thermostat (Figure 39-9). It makes a small amount of heat during the heating cycle to fool the thermostat into shutting off early. A heating anticipator reduces the system overshoot in furnaces caused by this cool-down. Figure 39-10 shows the effects of a heat anticipator on a mechanical thermostat.

Lag describes a delayed system response to a change in temperature. Mechanical thermostats use cooling anticipators to fool the thermostat into starting early. A cooling anticipator is a resistor with a high resistance that is wired in parallel with the cooling thermostat (Figure 39-9). They provide a path through the cooling controls during the off cycle, producing a small amount of heat to fool the thermostat into closing early. This reduces system lag by giving the system time to build system pressures and purge warm air out of ductwork before the cool air is needed.

Electronic thermostats have largely replaced the mechanical thermostats. They can sense temperature in tenths of a degree. Electronic thermostats do not use traditional heating or cooling anticipators. Instead, they use improved sensing, timing, and logic rather than false heat to reduce system swing. A well-designed electronic thermostat for a relay control system can keep the temperature swing within a degree.

Even proportional controls have a temperature swing between the minimum and maximum temperature in the room. Proportional controls can use feedback to modify their response to changes in room temperature. Electronic controls have the ability to adjust the feedback to the control to maintain a closer tolerance. One approach is called proportional integral derivative, or PID. A PID control uses programming and math to “learn” the response of the system and reduce the difference between the setpoint and the measured condition. Electronics have made PID control possible, allowing much closer control. DDC controls use PID and advanced programming and computer logic to maintain temperatures within tenths of a degree of setpoint.

39.5 LINE-VOLTAGE CONTROL SYSTEMS

Small appliances and commercial refrigeration systems with fractional horsepower motors often use line-voltage control systems. A line-voltage control system operates on the same voltage supplied to the unit. The switches in a line-voltage control system break the line-voltage power to the components they are controlling. The thermostats, pressure switches, and other controls in a line-voltage system must be able to carry the voltage and current of the motors they are controlling. They are rated by the voltage and current they can safely switch.

39.6 WINDOW-UNIT DIAGRAM

Window-unit air conditioners typically consist of a compressor and fan motor controlled by a selector switch and a thermostat. Figure 39-11 shows a diagram for a window unit. The switch is in series with both the fan motor and the compressor, while the thermostat is in series with the compressor.

Figure 39-12 shows the selector switch and thermostat from a typical window unit. The switch has connections for incoming line voltage (L); the low (1), medium (2), and high (3) speeds of the fan motor; and the thermostat (4) (Figure 39-13). The unit has two operating modes controlled by the switch: fan only and cooling.

In the low-fan or high-fan modes, the switch completes the circuit to either the low speed or high speed of the fan motor. There is no circuit to the thermostat connection (Figure 39-14). In fan mode, the fan runs continuously and the compressor does not run.

In low cool, medium cool, or high cool, the switch completes a circuit to the low (1), medium (2), or high (3) speed of the fan motor and also to the thermostat connection (4). In cooling mode, the fan runs continuously and the compressor cycles on and off with the thermostat (Figure 39-15).

39.7 WALK-IN FREEZER DIAGRAM

Figure 39-16 shows the diagram for a walk-in freezer. The freezer has four main loads: compressor, condenser fan motor, evaporator fan motor, and defrost heater. The

Figure 39-10 Heat cycle with anticipator.

Letters	Component

Figure 39-12 Selector switch and thermostat for window unit air conditioner.

compressor and condenser fan motor are cycled by the thermostat. The compressor is protected by both low-pressure and high-pressure switches in series. An additional close-on-rise pressure switch controls the operation of the condenser fan motor. The condenser fan motor does not operate until the head pressure exceeds the cut-in point of the fan cycling pressure switch.

The evaporator fan motor is in series with the open-on-rise contacts of the defrost termination thermostat. It runs all the time, except at the end of a defrost cycle. The defrost timer motor runs all the time. It has two sets of contacts: a normally closed set in series with the compressor and condenser fan motor, and a normally open set in series with

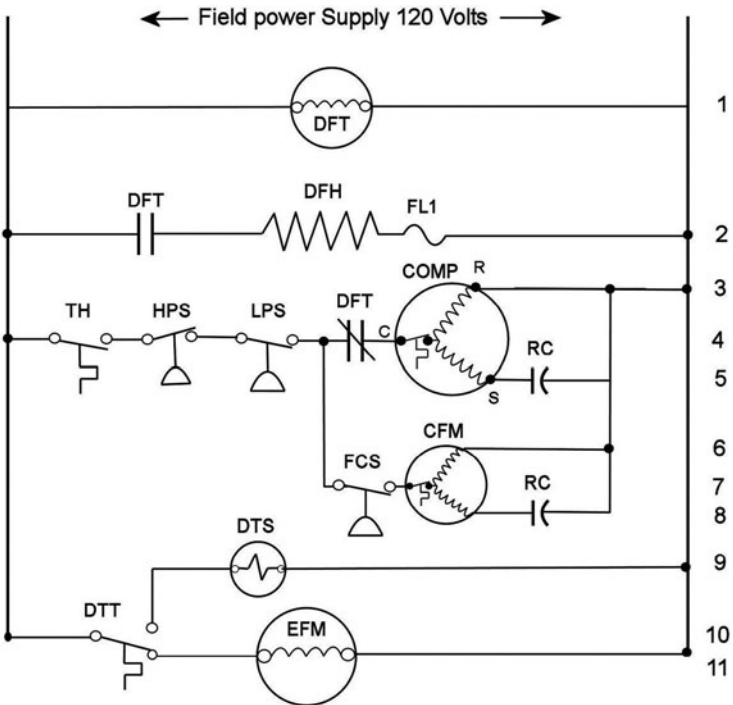

Figure 39-16 Diagram for walk-in freezer.

the defrost heater. When the defrost timer indicates that it is time to defrost, the normally closed DFT contacts open, breaking the circuit to the compressor and condenser fan motor. The normally open DFT contacts close, completing the circuit to the defrost heater. When the coil has defrosted, the defrost termination thermostat will switch positions, energizing the defrost termination solenoid and breaking the circuit to the evaporator fan motor. The defrost termination solenoid returns the defrost timer contacts to their normal position, energizing the compressor and breaking the circuit to the defrost heater. When the coil has dropped below freezing once again, the defrost termination thermostat returns to its normally operating position, making a circuit once again to the evaporator fan motor.

39.8 PUMP-DOWN CYCLE DIAGRAM

Refrigeration systems that must operate in cold weather often have a problem with refrigerant migration to the compressor during the off cycle. Refrigerant migration occurs when refrigerant travels to the compressor crankcase and dissolves itself in the compressor oil. When the compressor

starts, the refrigerant boils out violently, creating foam similar to when a carbonated beverage is shaken and then opened. While migration is a problem with all refrigeration systems, it is worse when the compressor is cold. One way to prevent off-cycle migration is to pump the refrigerant out of the low side of the system every time the system shuts off so there is no refrigerant to migrate to the compressor. Figure 39-17 shows a diagram for a basic pump-down system.

A pump-down control system requires a normally closed liquid-line solenoid valve and a pressure switch. The control thermostat actually controls the liquid-line solenoid valve instead of the compressor. When the thermostat is satisfied, it opens and de-energizes the solenoid (Figure 39-18). The solenoid shuts, stopping the flow of liquid to the evaporator. The compressor continues to run, but with no more refrigerant flow to the evaporator, the low-side pressure begins to drop as the refrigerant is pumped out of the evaporator. When the low-side pressure reaches the cut-out setting on the low-pressure switch, the pressure switch opens and breaks the circuit to the compressor (Figure 39-19). Typically this setting is above 0 psig to ensure that the system does not pull into a vacuum, which could possibly

Figure 39-17 Refrigerant pump-down circuit.

Figure 39-19 Pressure switch controlling the compressor.

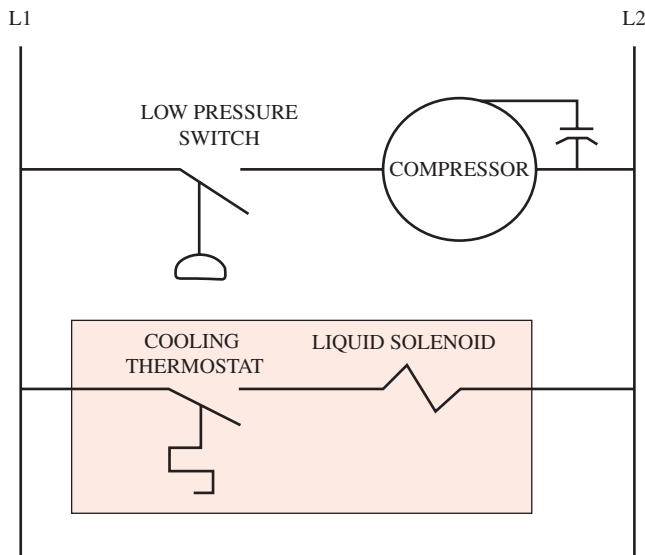

Figure 39-18 Thermostat controlling the pump-down solenoid.

damage the compressor or suck air into the system through any low-side leaks.

The system then waits for the next call for cooling. When the box temperature rises, the thermostat closes, energizing the solenoid. The solenoid opens, allowing refrigerant to flow into the low side of the system. When the pressure reaches the low-pressure switch cut-in setting, the pressure switch closes and starts the compressor.

39.9 LOW-VOLTAGE CONTROL SYSTEMS

Most residential heating and cooling equipment use low-voltage control systems. Low-voltage control systems typically operate on 24 V AC supplied by a control transformer. Control circuits must have a path from one side of the transformer secondary, through a low voltage load, and back to the transformer. The transformer supplies 24 V to a low-voltage

thermostat that controls the overall operation of the system. The side of the transformer secondary feeding the thermostat is known as the red side. A low-voltage thermostat does not control the loads directly. Instead, the thermostat controls relays and contactors that then control the motors in the air-conditioning equipment. The relays and contactors are all wired back to the common side of the transformer. It is called the common side because all of the control components have it in common.

39.10 TERMINAL CONNECTIONS

Most manufacturers of thermostats and central systems use a standard terminal identification such as shown in Table 39.1. Standard practice is to use wire colors that match the letter designations: red on R, yellow on Y, and so on. This makes wiring the controls much easier. However, technicians will often find that the thermostat wire that was provided does not contain the exact colors they need.

TECH TIP

Some terminal identification letters are closely associated to the color of wire often used. For example R is often red, W is often white, G is often green, and Y may be yellow; however, not all thermostat control wires contain the same color wires.

Thermostat wire is available in 18- and 20-gauge sizes. The smaller 20-gauge wire may result in a significant voltage drop in the control circuit if the wire run is extremely long. It is therefore recommended that you use 18-gauge wire for any long run. The control wire between the air handler and the condensing unit on a split-system air conditioner is usually a two-wire bundle that contains a red and a white wire. Most heat pumps use thermostat wire with six wires in the bundle: red, white, green, yellow, blue, and

Table 39.1 Standard Terminal Identification for Thermostats

Terminal Identification*	Function
R	Power from transformer
RC	Power from cooling-only transformer
RH	Power from heating-only transformer
C	Common from transformer
X	Same as common from transformer
W	Heat valve or relay
W1	First-stage heat
W2	Second-stage heat
Y	Compressor contactor
Y1	First-stage cooling
Y2	Second-stage cooling
G	Fan relay
B	Heat pump changeover valve to heating Alternate use: common on some systems
E	Emergency heat relay
L	Lamp

orange. For systems requiring larger bundles of conductors in the thermostat wiring, wire manufacturers provide wire bundles with nine and twelve conductors.

TECH TIP

Although the thermostats are often marked with color coded terminals, not all thermostat wiring has the same colors available. It is important when connecting a new thermostat that you reconnect the same terminal identification with the wire previously used for that function. When replacing a thermostat, one way to avoid confusion is to write down the terminal each wire color is connected to before disconnecting anything.

SERVICE TIP

With the thermostat removed from the subbase, you can usually read 24 V from the R terminal on the sub-base to most of the other terminals. That is because the other terminals feed controls that are wired to the common side of 24 V. The meter lead on the B, O, W, Y, and G terminals can read the common side of the transformer through the coils. With no current flowing through the circuit, there is no voltage drop through these controls, so they act just like a wire.

Letters	Component
CC	Compressor contactor
GV	Gas valve
IFM	Indoor fan motor
IFR	Indoor fan relay

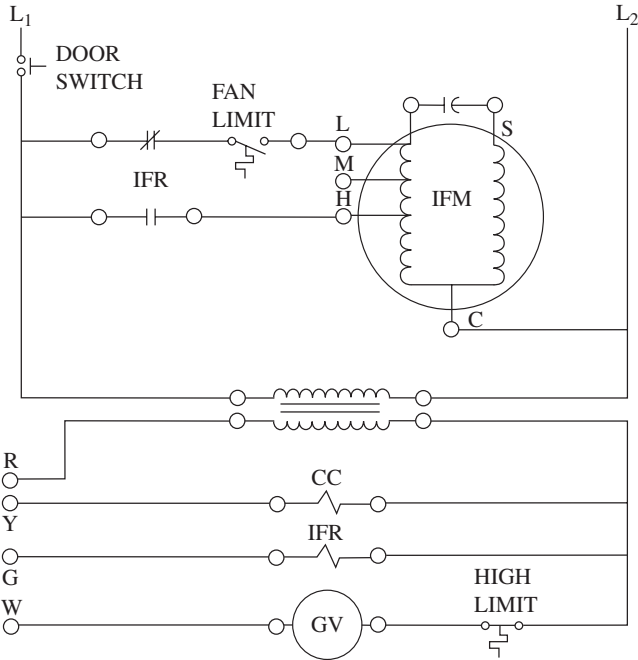

Figure 39-20 Standing pilot gas furnace ladder diagram.

39.11 STANDING PILOT GAS FURNACE DIAGRAM

Figure 39-20 is a ladder diagram of a basic standing pilot gas furnace with central air conditioning. With the system power on and the door switch closed, L1 voltage can be read at the fan switch and at the L1 terminal of the transformer (Figure 39-21). L2 voltage potential can be measured at all of the indoor blower motor (IFM), terminals. It can be read at all of the terminals because without a current flow there is no voltage drop across the motor. L2 voltage can also be measured at the second power lead of the transformer. There is a voltage drop across the primary of the transformer because the transformer is energized any time the system is on and the blower compartment door switch is closed. The transformer provides power to the R terminal on the thermostat. With the thermostat set to off, the transformer common can be read on both sides of the cooling contactor coil, indoor fan relay coil, gas valves, and limit switch. This means that on the thermostat's sub-base a voltage can be read from R to Y, R to G, and R to W.

When the system is in heating, as illustrated in Figure 39-22, L1 voltage can be read on the low, medium, high, and start leads of the indoor blower motor. There is a voltage drop across the motor from the common terminal to all three-speed terminals and the start terminal. A voltage

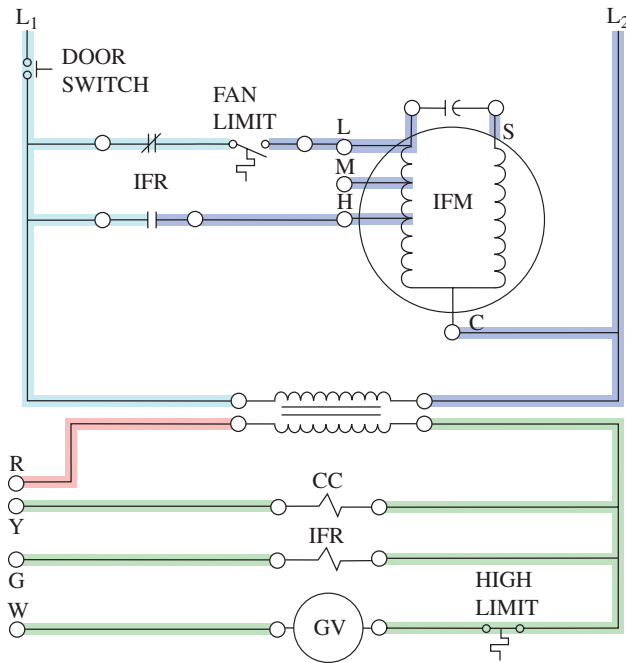

Figure 39-21 Gas furnace with power on but unit not operating.

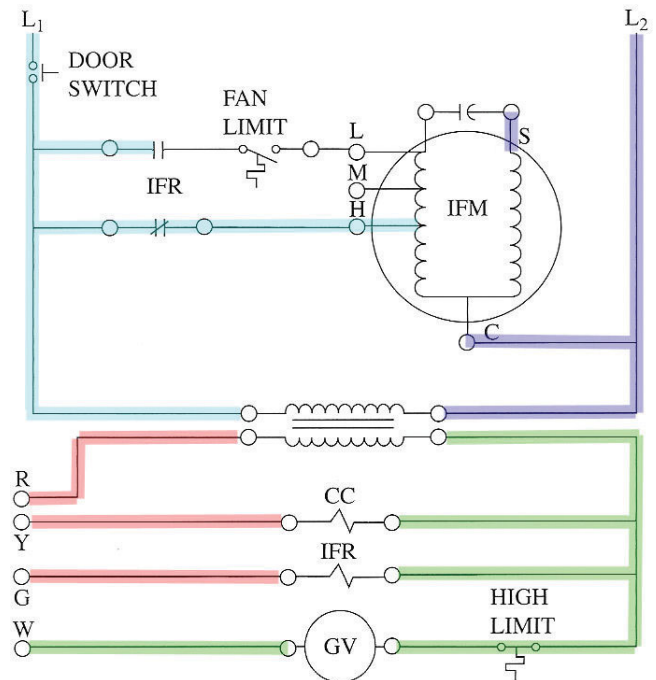

Figure 39-23 Gas furnace operating in cooling.

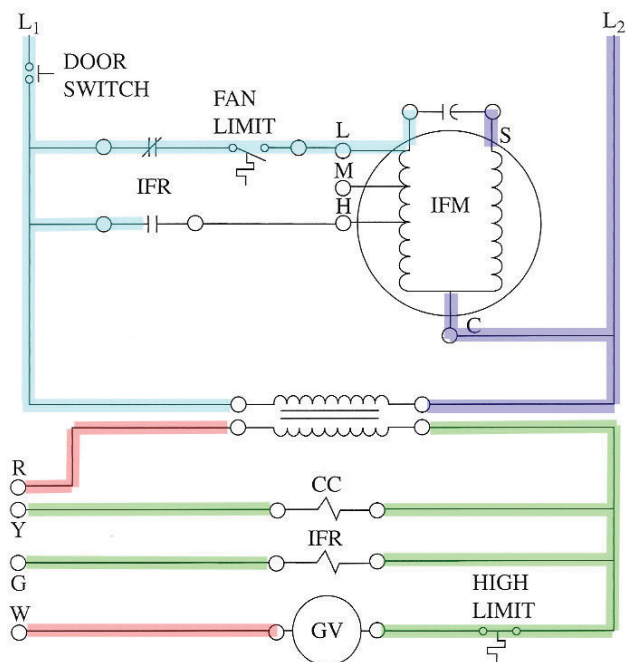

Figure 39-22 Gas furnace operating in heating.

drop can be measured across the primary windings of the control voltage transformer. A voltage drop can be measured across the gas valve, but no voltage drop will occur across the compressor contactor or indoor fan relay (IFR) because those circuits are not energized.

If the high-limit switch opens, a voltage drop would occur across the high-limit terminals and no voltage drop would be measured across the gas valve terminals. There would be no voltage drop on the gas valve because there

would not be a current flow through the open high limit. It is important to note that the fan switch would remain closed even though the gas valve is off so that the fan can continue to blow out the excessive heat from the furnace.

When this system is in cooling (Figure 39-23), the indoor blower relay contacts reverse so that the indoor blower motor is operating on high speed. The fan limit switch would remain open since there is no fire in the furnace to cause that temperature switch to close. There would be a voltage drop measurable across the compressor contactor and indoor blower relay. There would not be a voltage drop measurable across the gas valve because the gas valve would not be energized.

39.12 HOT SURFACE IGNITION GAS FURNACE DIAGRAM

Most gas furnaces manufactured today do not use a pilot light. Instead, they ignite the main burners directly using a hot surface igniter. Figure 39-24 shows a ladder diagram for a gas furnace with hot surface ignition. The draft fan relay (DFR), ignition relay (IR), cooling fan relay (CFR), and heating fan relay (HFR) are all part of the ignition control. The ignition control is shown in two places on the diagram because it is involved in both line voltage circuits (lines 1–6) and low-voltage circuits (lines 10–17). However, the ignition control is one physical device. Splitting it in two preserves the integrity of the ladder diagram.

With the system switch in the heat position, the heating thermostat closes when the room temperature drops. This initiates a call for heat, creating a path from the R side of the transformer to the W terminal on the thermostat, through the limit and roll-out switches to the ignition control (Figure 39-24) (line 14). The ignition control energizes the DFR coil

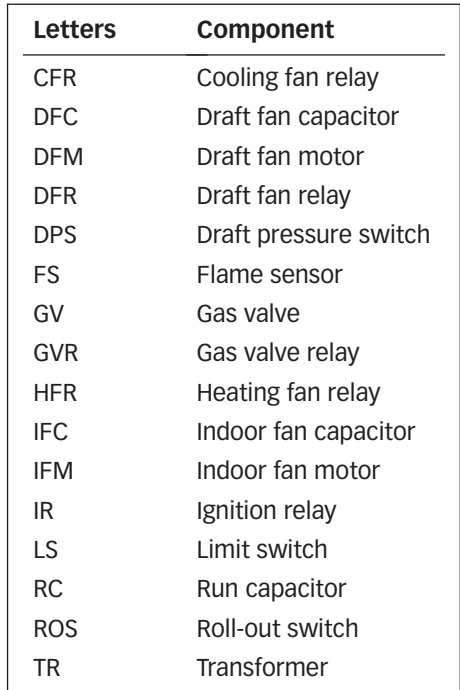

Figure 39-24 Diagram for hot surface ignition furnace.

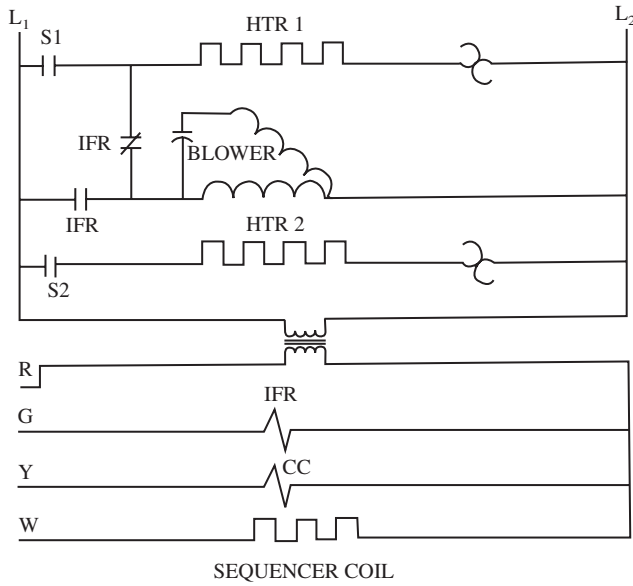

(line 14), closing the DFR contacts, which energize the draft fan motor (DFM) on line 3. The DFM operates for 60 seconds to perform a pre-purge. The pre-purge removes any lingering gas or combustion products from the burner and heat exchanger. Operation of the DFM causes the draft pressure switch (DPS) to close. After the pre-purge, the ignition control checks to see if the DPS is closed (line 13). The ignition process does not continue until the DPS closes. After the ignition control sees that the DPS is closed, it energizes the ignition relay (IR) on line 16, closing its contacts and energizing the igniter (line 1). The igniter is energized for 60 seconds before the gas valve is energized. The gas valve is energized and the flame rectification circuit looks for the presence of flame (line 12). If flame is sensed, the gas valve remains energized and the igniter is de-energized. If flame is not sensed, both the gas valve and igniter are de-energized after 5 seconds. The heating fan relay coil (HFR) on line 17 is energized after a delay of 2 to 3 minutes. The normally open HFR contacts close to energize the heating fan speed and the normally closed HFR contacts open to prevent operation of the cooling fan speed (Figure 39-24) (lines 5 and 6). Starting of the indoor

fan motor is delayed to allow the furnace time to heat up. This prevents the fan from blowing cold air into the house.

39.13 ELECTRIC FURNACE DIAGRAM

Figure 39-25 is a ladder diagram of a two-element electric furnace diagram that has central air conditioning. Figure 39-26 shows the part of the circuit that is energized with line 1 and line 2 potential voltages.

Figure 39-27 illustrates all of the circuits that would be energized when the first-stage heating element has come on. Note that there is not a voltage drop across the second-stage heating element at this time. Only the first-stage heat and fan are operating. On the secondary circuit, the sequencer heat motor element has been energized. Figure 39-28 shows the parts of the circuit that would be energized when both the first- and second-stage heating elements have been energized. When the second set of contacts close on the second-stage heating circuit, all of the elements are energized and show a voltage drop.

Letters	Component
CC	Compressor contactor
GV	Gas valve
HTR 1, HTR 2	Heater 1, heater 2
IFR	Indoor fan relay

Figure 39-25 Electric furnace ladder diagram.

Figure 39-29 represents those circuits that would be energized when the system is in the cooling mode. Note that the heating elements are not energized and that the indoor fan relay (IFR) has opened the contacts to the first-stage heating element as the normally opened contacts are closed so that the indoor blower motor is operating. On the secondary there is a voltage drop across the indoor blower motor relay and the outdoor compressor contactor.

Figure 39-31 Ladder diagram of condensing unit with power on and system off.

39.14 CONDENSING UNIT DIAGRAM

The basic condensing unit consists of a compressor, fan motor, capacitors, and contactor (Figure 39-30). With line voltage to the unit but no call for cooling, the line voltage stops at the contactor. Typically the common side of the transformer secondary is wired directly to one side of the contactor coil. The R side of the transformer secondary is controlled by the thermostat. When the thermostat is not calling for cooling, the R side of the transformer stops at the thermostat. The thermostat breaks the circuit, so there is no current flow. With no current flow there is no voltage drop through the coil, so the coil acts like a wire. This means that the common side of the transformer is available at both sides of the coil and at both control wires to the coil. On the diagram, both wires and both sides of the coil are shaded the same color. The contactor coil is not operating, and no voltage is read at the contactor coil (Figure 39-31).

When the thermostat closes and calls for cooling, the R side of the transformer is connected to one side of the coil. Now a voltage drop of 24 V can be read across the contactor coil. This is indicated by the change in color. The contactor coil is energized.

Energizing the contactor coil closes the contactor's normally open points and the voltage from L1 passes through the closed contacts to T1 to the common leads of both the compressor and fan. The voltage from L2 passes through the closed contacts to T2 and onto the run terminals of the compressor and fan (Figure 39-32).

Figure 39-33 is of a wiring diagram for a condensing unit that uses a dual (three-terminal) run capacitor. When line voltage is supplied to the unit, line voltage between L1 and L2 can be measured up to the contactor. A voltage measurement between the two terminals of the contactor would read 208–240 V depending on the supply voltage. The control voltage to terminals Y and C would read 0 V.

Figure 39-32 Ladder diagram of condensing unit with power on and system on.

When the cooling contacts in the indoor thermostat close, the circuit is completed to the outdoor compressor contactor coil providing 24 volts to terminals Y and C. The coil then closes the compressor contactor contacts, allowing L1 voltage passes across the contacts to the common terminals on the compressor and fan. At the same time, L2 voltage passes through the closed compressor contactor contacts to the C terminal on the dual capacitor, the run terminal on the compressor, and the main winding on the outdoor fan motor. The compressor start terminal receives voltage from the H terminal on the dual capacitor, and the outdoor fan motor auxiliary winding receives voltage from the F terminal on the dual capacitor.

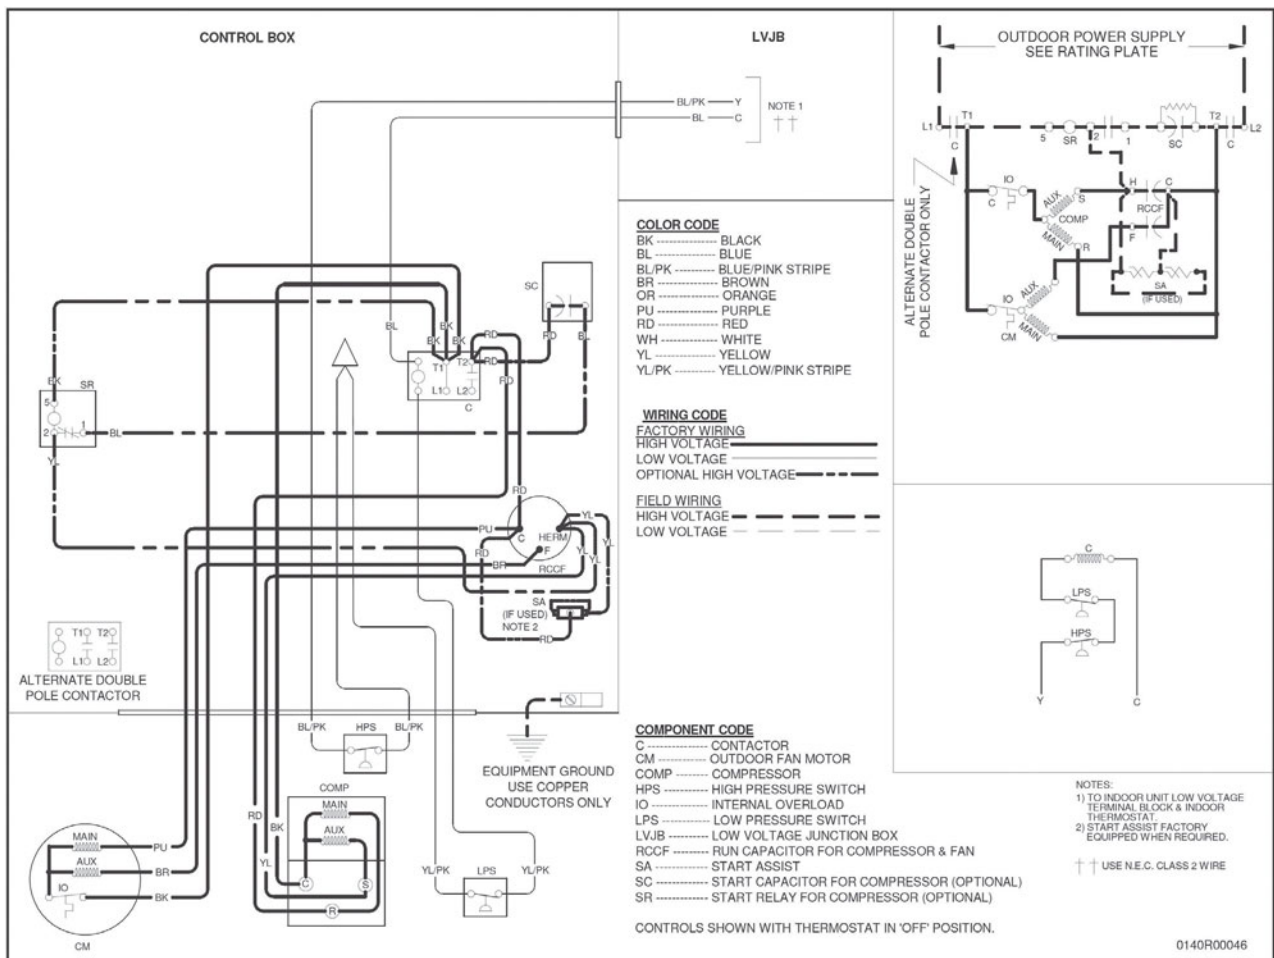

Figure 39-33 Schematic diagram for a dual-capacitor unit. (Courtesy of Goodman Global Group, Inc.)

39.15 POTENTIAL RELAY AND START CAPACITOR

Figure 39-33 also has a start capacitor and a potential start relay. The start capacitor improves the compressor motor starting torque. The start relay is used to take the start capacitor out of the circuit after the compressor starts. When this system is on and running, there is a voltage across the coil on the potential start relay (SR) between terminals 5 and 2. This measured voltage is higher than the applied line voltage between L1 and L2. This higher voltage is the result of the back electromotive force created by the compressor motor as the compressor runs. It is this higher voltage, or potential, that energizes the relay coil, opening the normally closed relay contacts located between terminals 1 and 2. This drops the start capacitor from the circuit within a fraction of a second as the compressor starts.

SERVICE TIP

If the contacts in the potential relay do not open, the current flowing through the start capacitor would quickly cause the start capacitor to overheat and explode!

39.16 HEAT PUMP COOLING CYCLE

Figure 39-34 shows a schematic diagram of a traditional air-source heat pump. A heat pump is essentially an air-conditioning system that can reverse the indoor and outdoor coils. The indoor coil is the evaporator in cooling and the condenser in heating. The outdoor coil is the condenser in cooling and the evaporator in heating. This is done by reversing the flow of refrigerant between the two coils using a reversing valve. The reversing valve can be energized in either the heating or cooling cycle, depending upon the manufacturer's design. This particular diagram energizes the reversing valve in the cooling cycle, as do more heat pumps today.

Moving the system switch to COOL sends 24 volts from R to O, energizing the reversing valve solenoid (RVS) on line 17, (Figure 39-34). When the room temperature increases, the cooling thermostat (TSC) closes, sending 24 volts from R to Y, energizing contactor coil C (line 16). If the fan switch is in the AUTO position, TSC also sends 24 volts to G, energizing the indoor fan relay (IFR), on line 15. The contactor coil closes its normally open contacts, energizing the compressor and outdoor fan motor (OFM) on lines 4–9. At the same time, the indoor fan relay (IFR) closes its normally open contacts, energizing the indoor fan motor (IFM) on line 11. All loads necessary to cool are now operating (Figure 39-35).

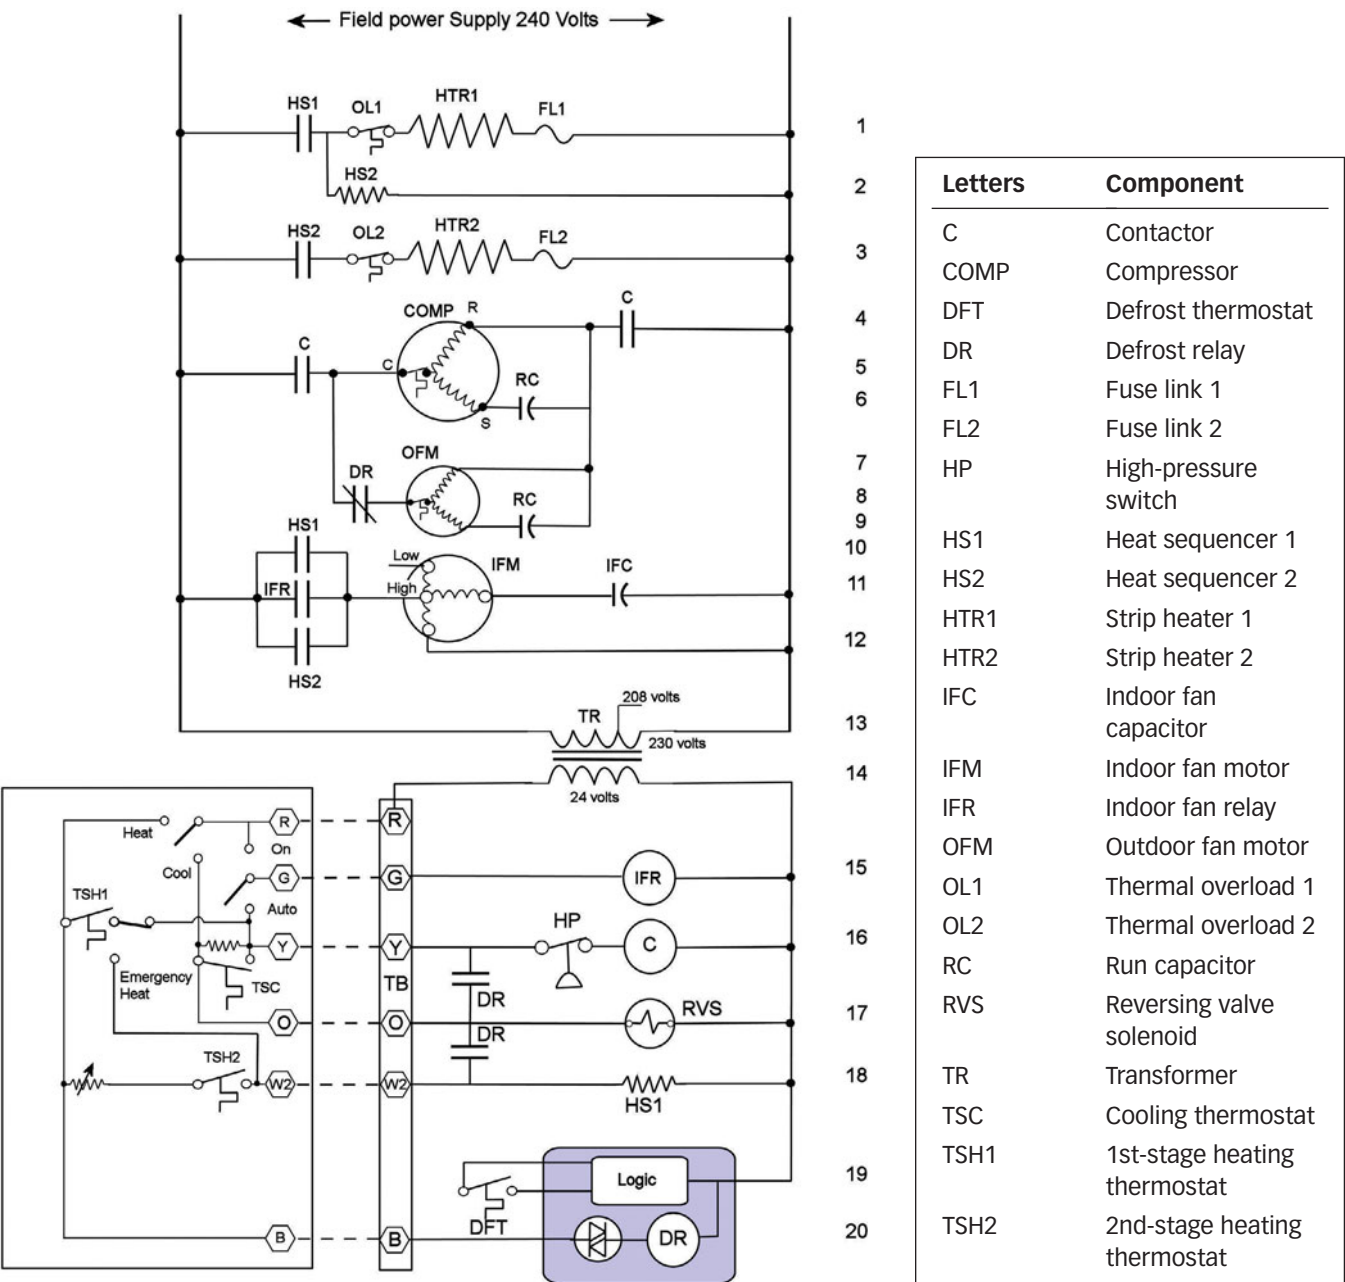

Figure 39-34 Diagram for air-source heat pump.

39.17 HEAT PUMP FIRST-STAGE HEAT CYCLE

The main difference between the cooling cycle and the first-stage heating cycle is the reversing valve. The reversing valve is not energized in heating on this diagram. Moving the system switch to HEAT sends 24 volts from R to B, energizing the defrost board (see Figure 39-34) (line 20). When the room temperature decreases, the first-stage heating thermostat (TSH1) closes, sending 24 volts from R to Y, energizing contactor coil C (line 16). If the fan switch is in the AUTO position, TSH1 also sends 24 volts to G, energizing the IFR (line 15). The contactor coil closes its normally open contacts, energizing the compressor and outdoor fan motor (lines 4–9). At the same time, the indoor fan relay closes its

normally open contacts, energizing the indoor fan motor (line 11). All loads necessary for first-stage heat are now operating (Figure 39-36).

SERVICE TIP

Although many systems use terminal B to energize heating-cycle components such as reversing valves or defrost boards, some manufacturers use terminal B as the common terminal. Wiring a thermostat heating terminal B to a heat pump common terminal B will burn out both the thermostat and the transformer when the system switch is moved to the HEAT position. You cannot depend

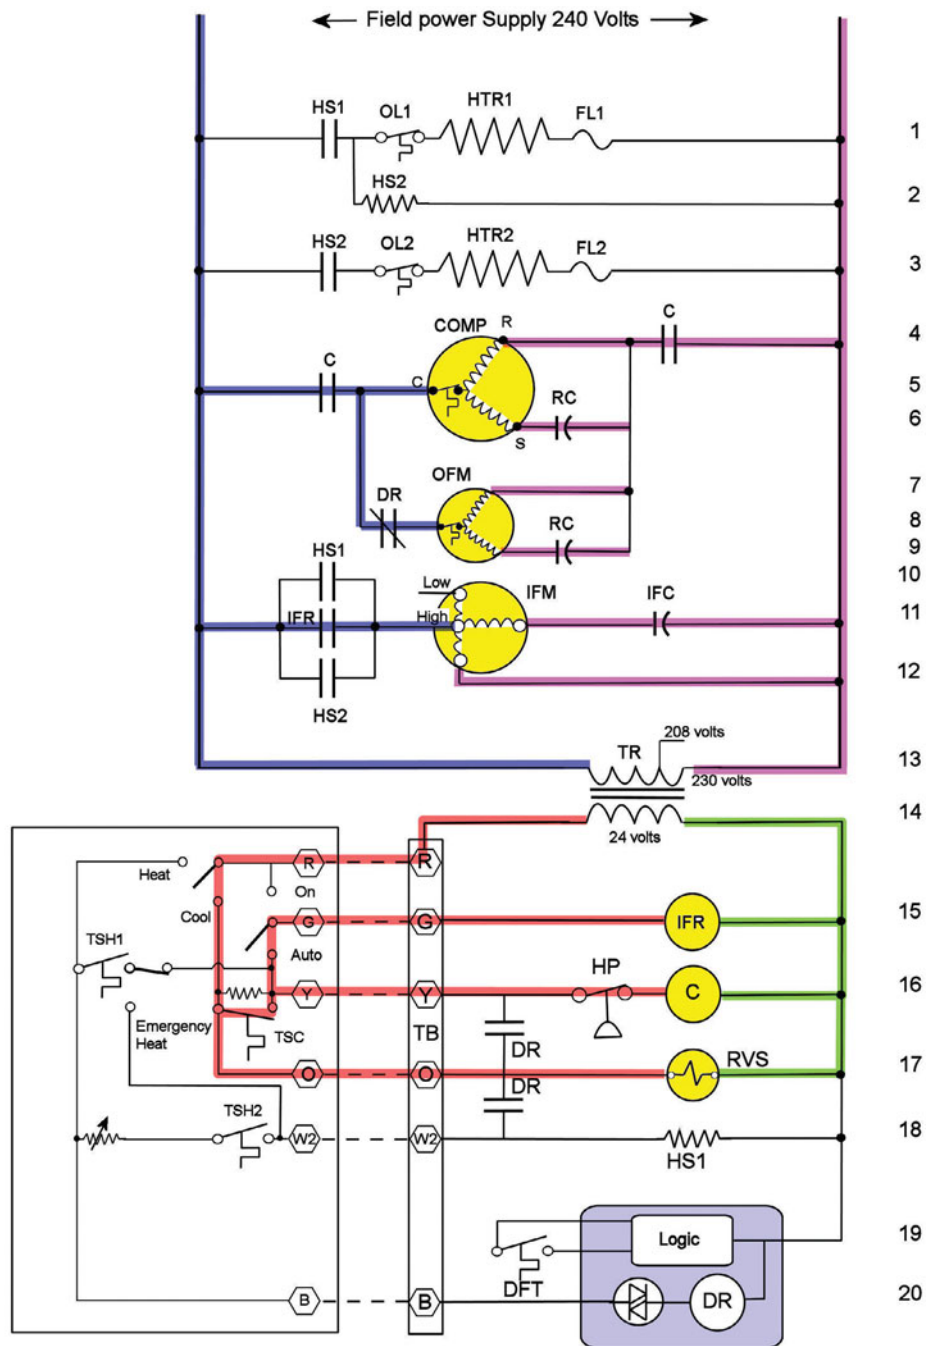

Figure 39-35 Heat pump operating in cooling cycle.

entirely on letters and colors when doing the control wiring. You have to read the instructions and refer to the diagrams on all connected pieces of equipment.

39.18 HEAT PUMP SECOND-STAGE HEAT CYCLE

The second-stage heating thermostat (TSH2) closes if the first-stage heat cannot maintain the room temperature within 1.5 degrees of the thermostat setpoint. TSH2 sends 24 volts from R to W2, energizing heat sequencer 1 (HS1)

(see Figure 39-36) (line 18). The HS1 coil is a small heater that warps a bimetal disk to close the contacts after a time delay of 30 seconds. HS1 has two sets of normally open contacts that close after a time delay to prevent the strips from energizing immediately at startup when the compressor and fan motors are drawing high starting amps. The HS1 normally open contacts close, energizing the first heater (HTR1) and the coil to the second heat sequencer (HS2) (lines 1 and 2). HS2 closes its contacts after a time delay to energize the second heater (HTR2) (line 3). Note that HS1 and HS2 normally open contacts are in parallel with the IFR contacts (lines 10 and 12). They ensure that the indoor fan motor will operate whenever the heat strips are operating.

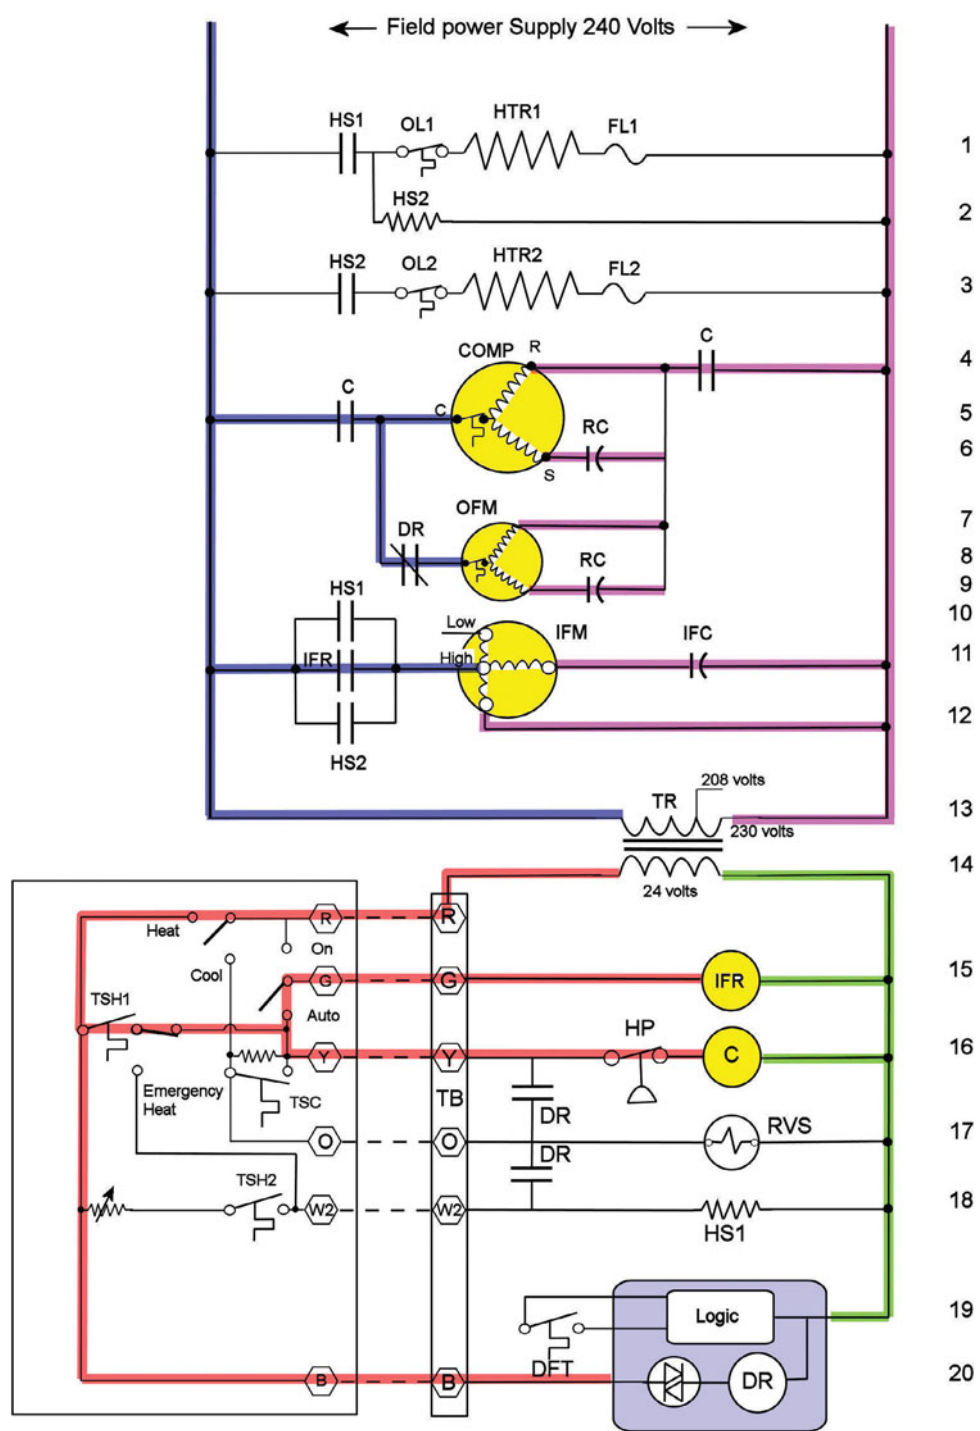

Figure 39-36 Heat pump operating in heating cycle.

All loads necessary for first- and second-stage heat are now operating (Figure 39-37).

39.19 HEAT PUMP EMERGENCY HEAT CYCLE

Air-source heat pump thermostats typically have an EMERGENCY HEAT selection on the system switch. Emergency heat disables the compressor heat and allows the second-stage

heat to cycle on the first-stage thermostat. This is useful if the refrigeration circuit is not operating correctly. The thermostat in this diagram accomplishes this through internal circuitry. Moving the system switch to EMERGENCY HEAT sends 24 volts from TSH1 to the W2 terminal instead of the Y terminal (see Figure 39-34) (line 16). When TSH1 closes, it energizes the HS1 coil (line 18). The HS1 contacts close, energizing HTR1 and the HS2 sequencer coil (lines 1 and 2). The second set of HS1 contacts close at the same time to energize the indoor fan motor (line 11). After a delay, the

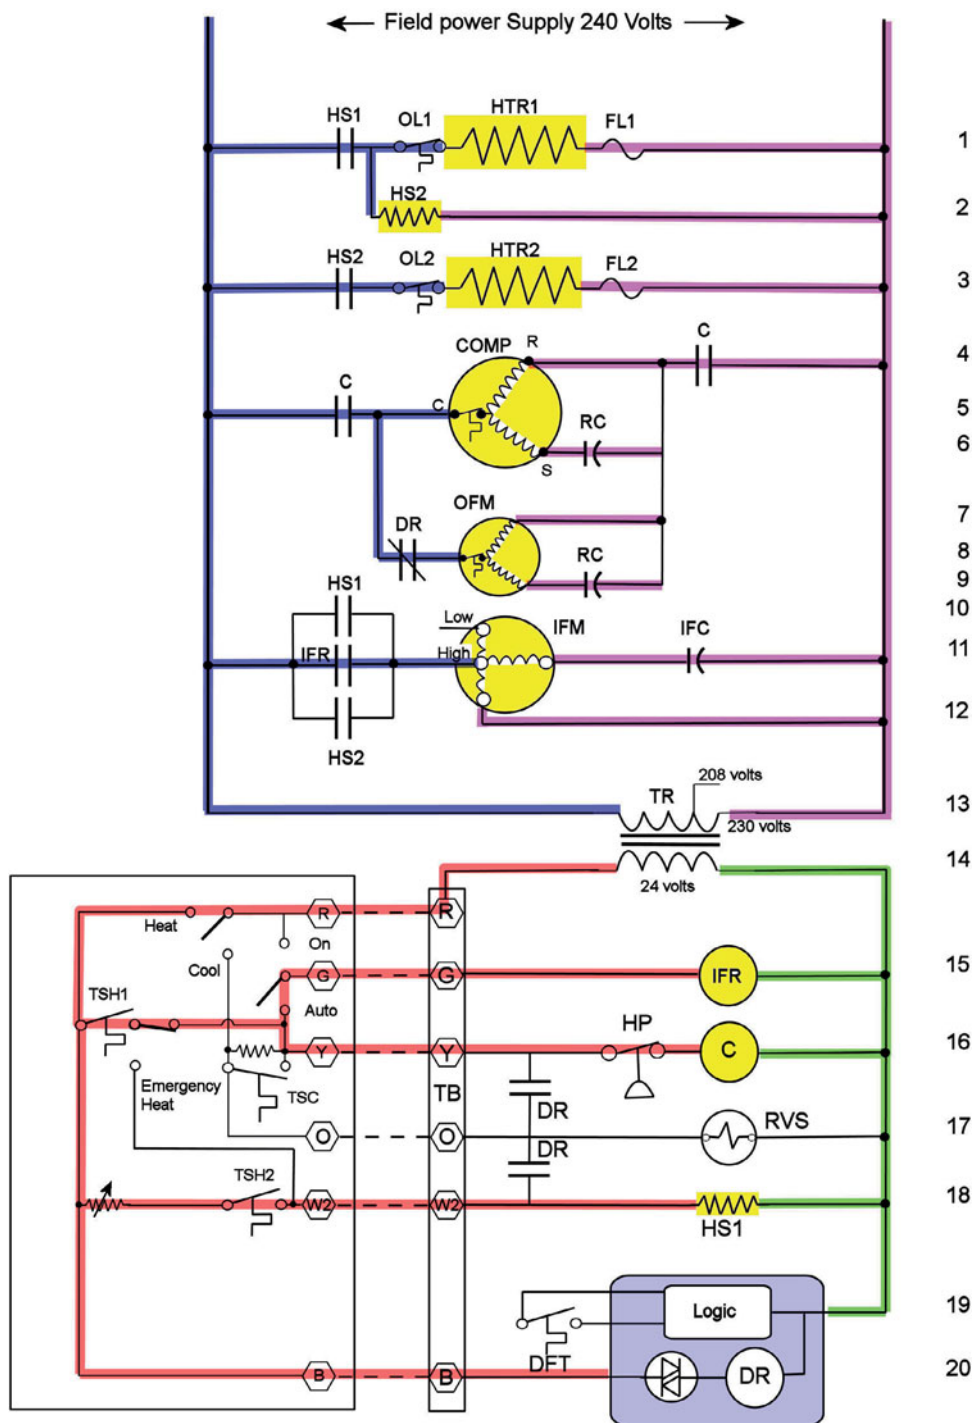

Figure 39-37 Heat pump operating in second-stage heat.

HS2 contacts close, energizing HTR2 (line 3). All loads necessary for emergency heat are now operating (Figure 39-38).

39.20 HEAT PUMP DEFROST DIAGRAM

Most modern heat pump defrost control boards serve as the central nervous system of the heat pump. All control signals pass through the defrost board. Thus the defrost board really controls more than simply the defrost function;

it controls all aspects of the heat pump condensing unit operation. Figure 39-39 shows a typical heat pump diagram. The connection diagram on the left shows the terminals on the defrost board, the wire colors, and exactly how the wires are routed on the unit. The schematic on the right shows the electrical circuitry and how the controls in the heat pump operate. The yellow shaded areas in Figure 39-40 represent the defrost board. Notice that the defrost board is shown as one piece in the connection diagram, but its functional parts are split up in the schematic diagram.

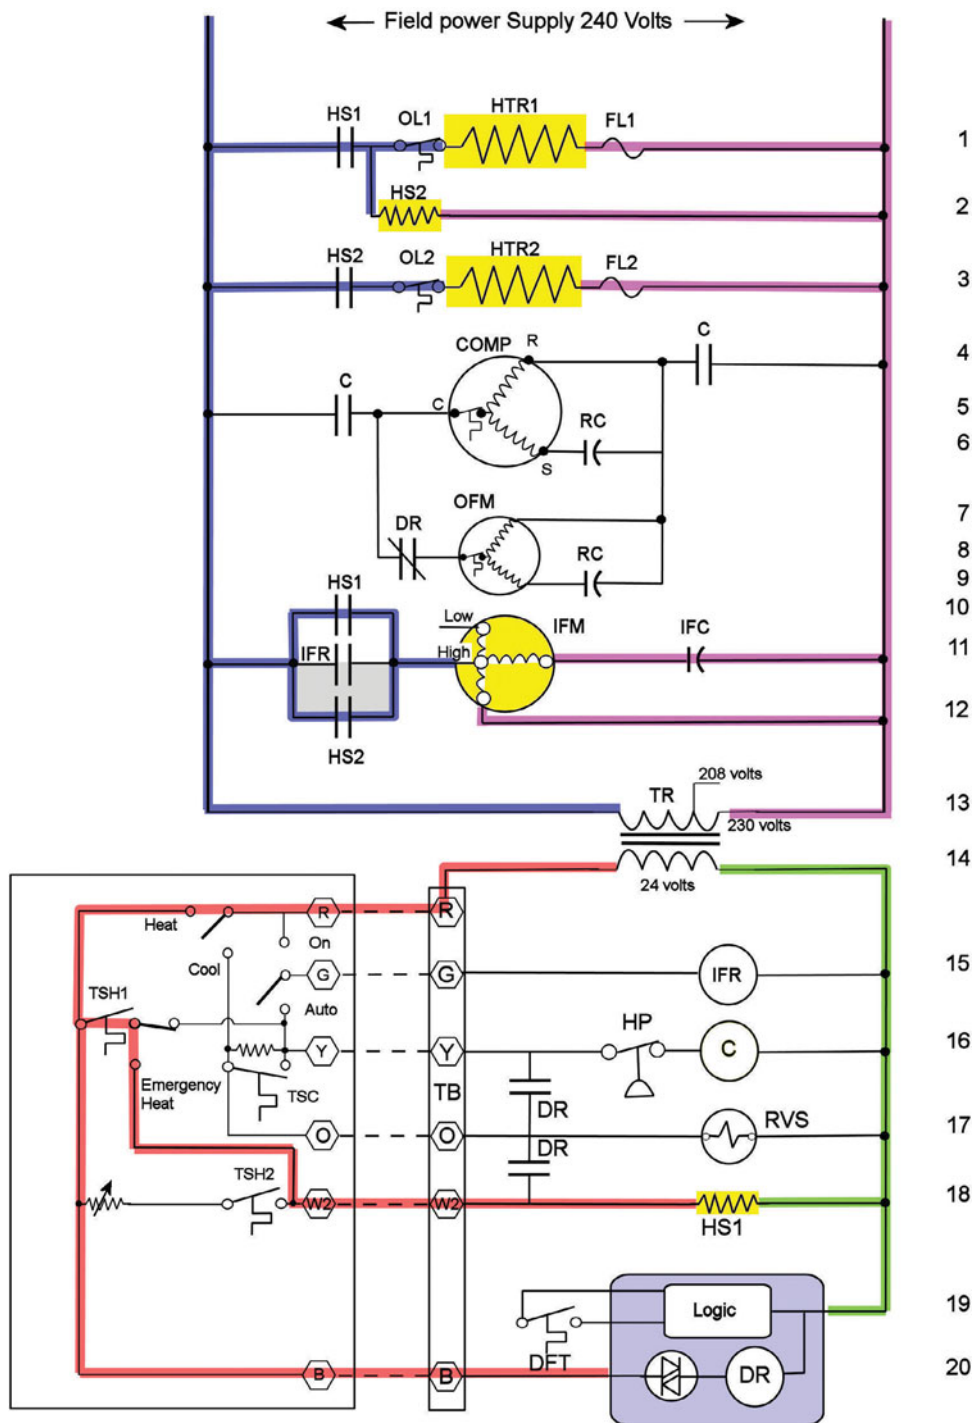

Figure 39-38 Heat pump operating in emergency heat.

To defrost the heat pump, the defrost control must accomplish three things:

- Shift the reversing valve from heating to cooling.
- Turn off the outdoor fan.
- Turn on the auxiliary heat.

The most frequently used method of determining when to initiate a defrost is based on time and temperature. The

defrost thermostat, shown in Figure 39-41, senses the outdoor coil temperature. When the coil temperature is below $30^{\circ}\text{F} \pm 3^{\circ}\text{F}$, the defrost thermostat completes a circuit to the logic in the defrost board (Figure 39-42). The defrost board will then start timing. When the timer reaches the elapsed time programmed by the jumper, a defrost cycle is initiated. However, if the defrost thermostat opens before the timing period is reached, the timer is reset. The system must operate for 30, 60, 90, or 120 minutes with the coil

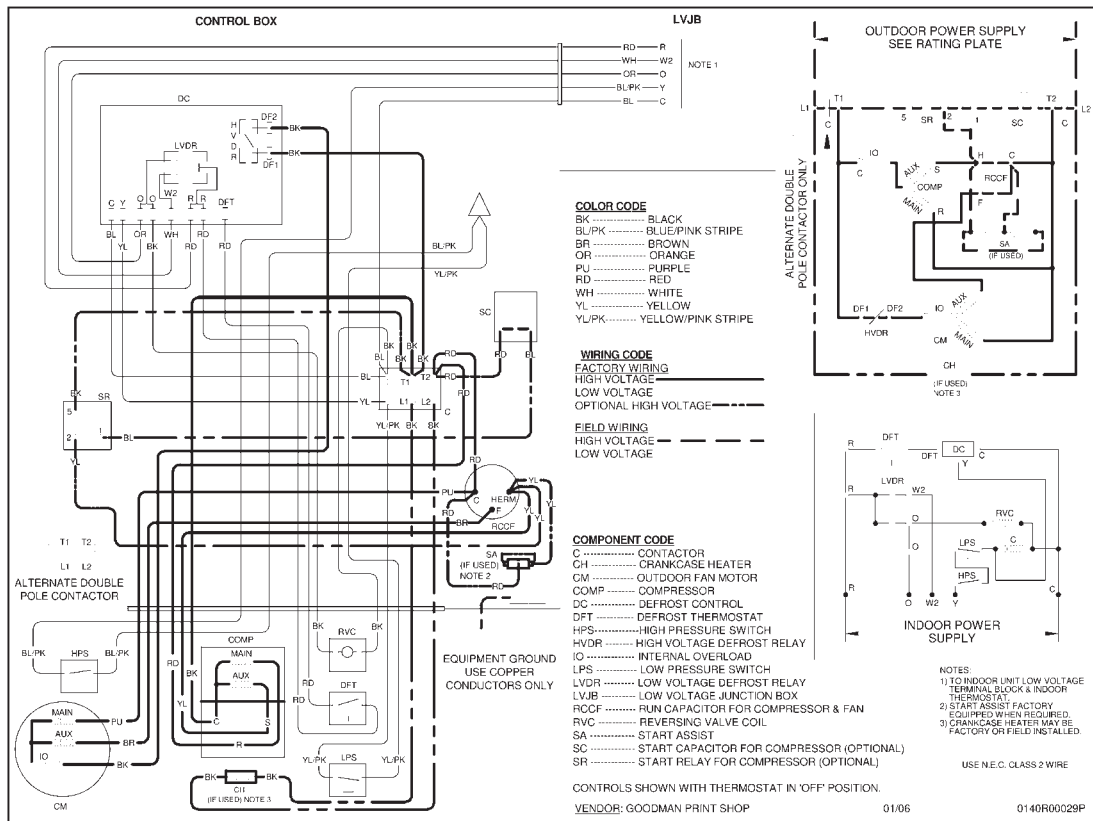

Figure 39-39 Heat pump schematic diagram. (Courtesy of Goodman Global Group, Inc.)

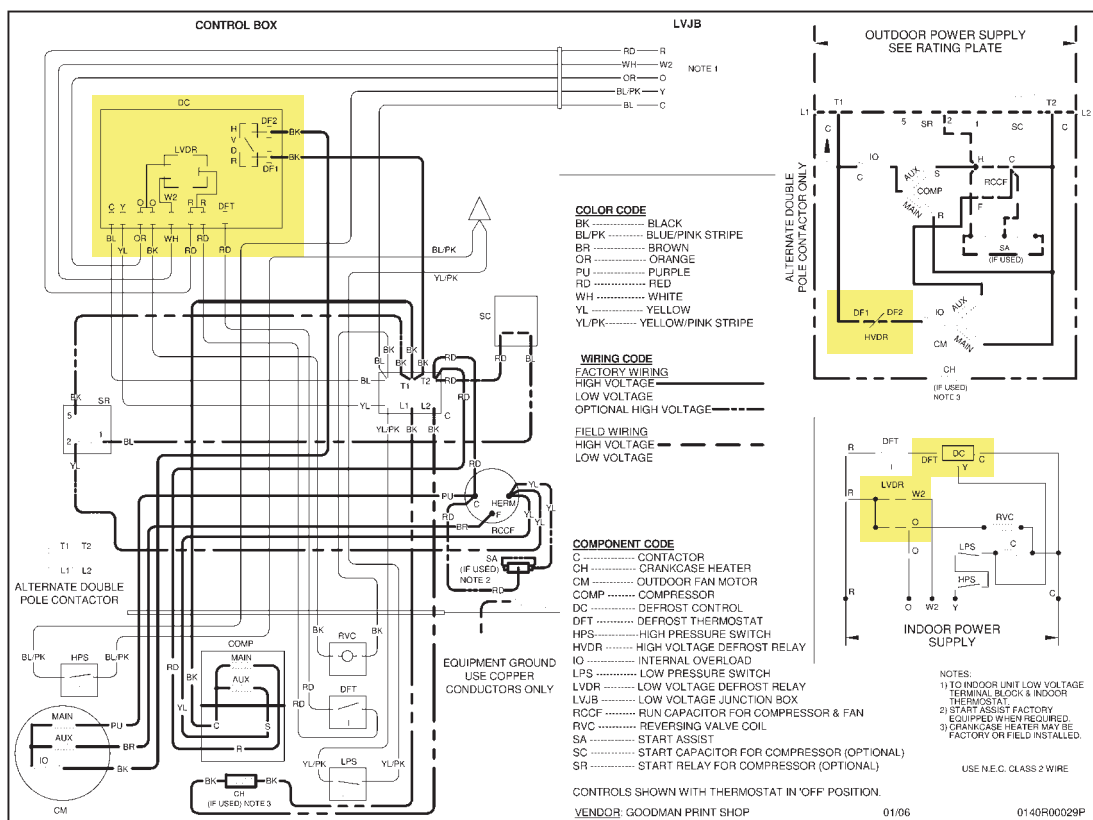

Figure 39-40 Defrost board on heat pump diagram. (Courtesy of Goodman Global Group, Inc.)

Figure 39-41 Defrost thermostat.

temperature below the defrost thermostat setpoint before a defrost cycle will be initiated. The defrost period will continue until the defrost thermostat opens around 80°F. The defrost cycle is terminated after 10 minutes if the defrost thermostat does not open.

Some heat pumps energize the reversing valve in heating, while others energize the reversing valve in cooling. Regardless of which method is used, the reversing valve must shift from heating to cooling for a defrost cycle. Today, more units energize the reversing valve in cooling than in heating. They typically use the O terminal to energize the reversing valve. For these systems, the reversing valve must be energized in defrost. Figure 39-43 shows the circuit that energizes the reversing valve in defrost. The normally open low-voltage defrost relay (LVDR) contacts close to complete a circuit from R to O and out to the reversing valve solenoid. The LVDR is actually part of the defrost board, not a separate relay.

The high-voltage defrost relay (HVDR) has a set of normally closed points that are wired in series with the outdoor fan. These can be seen in Figure 39-44. The outdoor fan is de-energized when the HVDR normally closed points open. Note that the HVDR is also a part of the defrost control board, not a separate relay. Also notice that the circuit to the outdoor fan is a line voltage circuit.

The circuit that energizes the auxiliary heat is shown in Figure 39-45. The normally open LVDR contacts close to complete a circuit from R to W2. This provides 24 volts to the auxiliary heat inside.

39.21 COMMERCIAL AIR CONDITIONER

Figure 39-46 shows the diagram for a light commercial air-conditioning system. Although light commercial units are similar to residential systems in many respects, the power supply, the increased size of the motors, and varying operating conditions require additional controls.

Motors

Most commercial systems use three-phase power, while residential systems are exclusively single phase. Frequently in light commercial equipment, the compressor is a three-phase motor and the fan motors are single phase, as in Figure 39-46. All the motors are three phase in larger commercial systems. All the motors in a commercial unit are normally controlled by contactors instead of relays. Each motor normally has its own contactor, or at least its own set of contacts. The condenser fan motors do not share a set of contacts with the compressor as in residential systems. In Figure 39-46, the compressor is controlled by the compressor contactor (lines 1–3), and the condenser fans are controlled by the outdoor fan contactor (lines 4–9). These changes are all due to the larger size of the motors.

Controls

The added size and number of the contactors makes it impractical to operate them with 24 V. The combined VA requirement would normally exceed the 100 VA limit for Class 2 control systems. The contactor coils in commercial systems normally operate on line voltage. They are controlled by the contacts of 24 V control relays. The relays can be considerably smaller in size than the contactors they control because the relay contacts only have to handle the current draw from the contactor coils, which is very low. These systems in effect have two control systems: a 24 V system of relays to control line voltage contactors that control the motors.

In Figure 39-46, the 24 V thermostat controls the indoor fan relay in line 18 and the cooling relay in line 19. The indoor fan relay contacts control the 230 V indoor fan contactor coil on line 15. The indoor fan contactor then closes to complete the circuit to the indoor fan motor on line 10. The cooling relay controls both the compressor contactor in line 12 and the outdoor fan contactor in line 14. The compressor contactor energizes the compressor in lines 1–3. The outdoor contactor closes to energize outdoor fan motor 1 on lines 4–6 and outdoor fan motor 2 on lines 7–9.

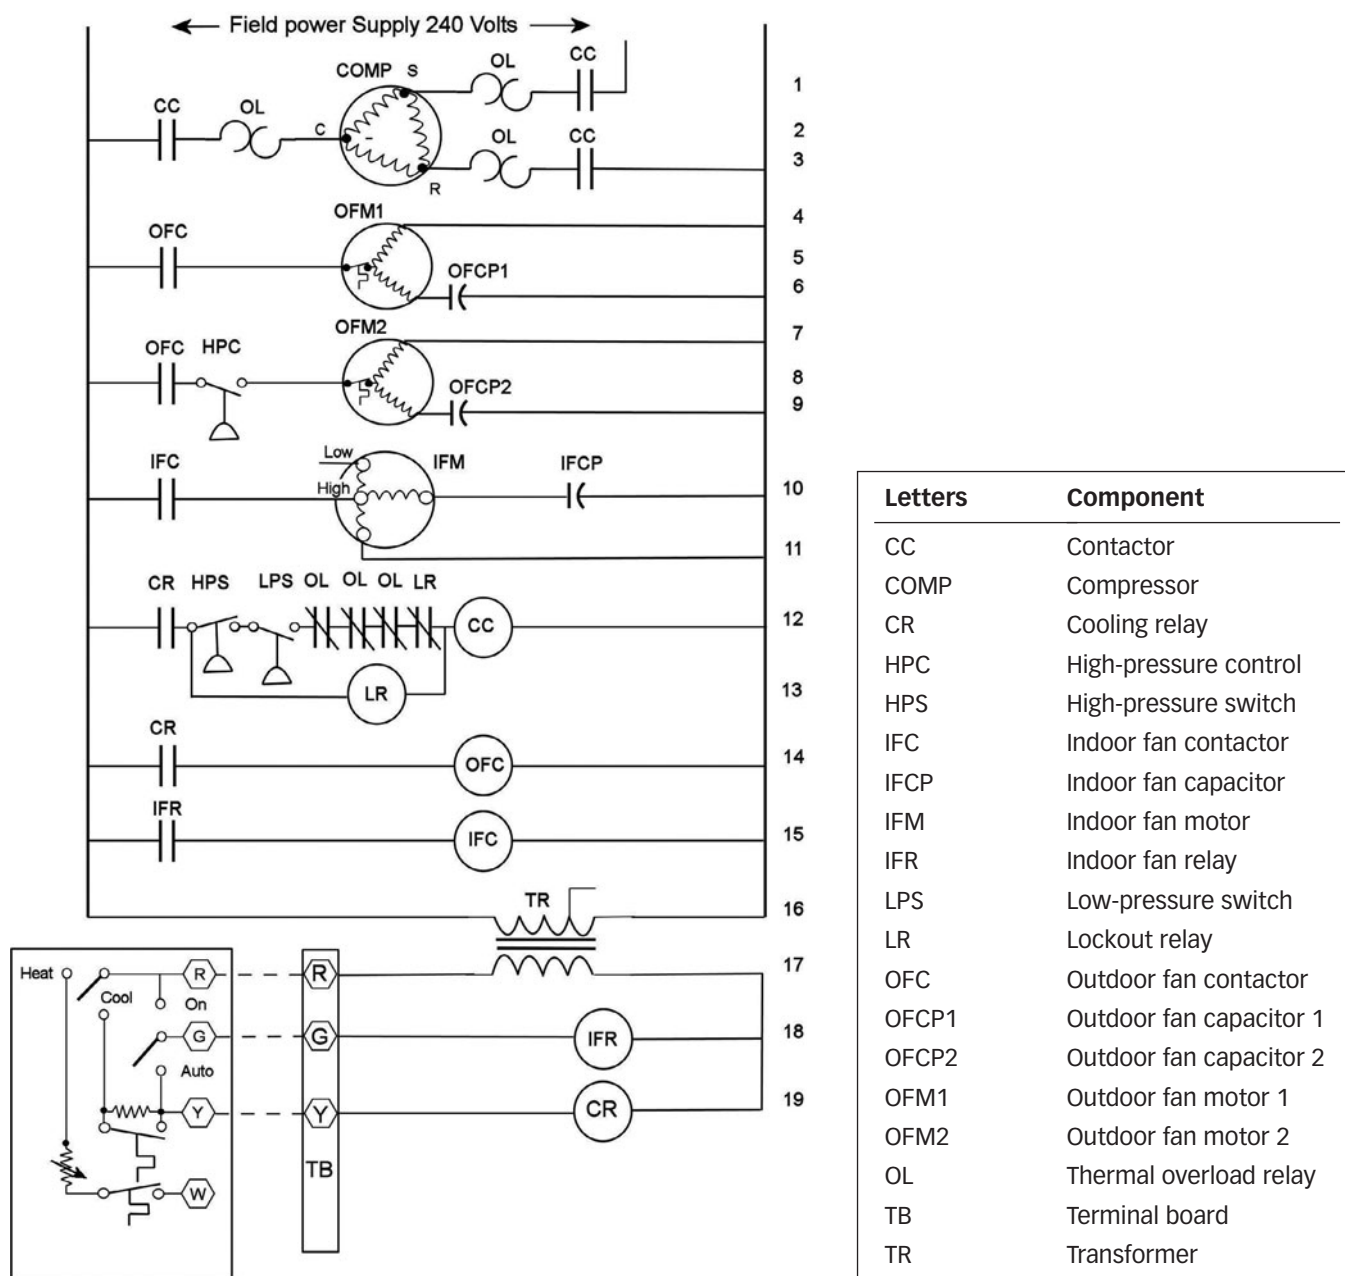

Figure 39-46 Diagram for light commercial air conditioner.

Low Ambient Operation

Residential air-conditioning systems seldom need to operate when it is cold outside. Commercial systems, on the other hand, frequently operate in cold weather. Commercial buildings often need cooling even in cold weather because of internal heat loads from lights, machines, and people. Operating air-cooled condensers with air temperatures significantly below design temperature can cause lower than normal high-side pressures, reducing the pressure difference across the refrigerant metering device. Most metering devices need some minimum pressure drop to function properly and will underfeed if the high-side pressure is too low. Commercial systems often use multiple condenser fans with one running whenever the system operates and

another running just when needed. In Figure 39-46, the second condenser fan is controlled by a close-on-rise pressure switch on line 8. When the condenser pressure increases enough to require a second condenser fan, the pressure switch closes and energizes the second condenser fan.

Safety Controls

Another big difference is the number of safety controls. Most commercial air-conditioning systems have a full complement of safety controls. The compressors are typically three-phase motors that cannot be protected by inline thermal overloads the way single-phase motors are often protected. Breaking a single line of power to a three-phase motor will cause more harm than good because each leg of

power is only in two of the three circuits. One circuit will be left operating, trying to carry the load by itself. This condition is caused single-phasing and quickly leads to motor burnout because the amp draw in the remaining windings doubles, quickly overheating the motor. Overload relays are used instead of inline overloads. An overload relay has a coil that senses the overload and a set of normally closed contacts that open when the coil senses an overload. The coil is in series with the motor and the contacts are in series with the coil for the motor control. In Figure 39-46, the compressor is protected by an overload relay in all three legs of power in lines 1–3. The normally closed overload contacts are in series with the compressor contactor coil (CC) in line 12. When an overload is sensed in any of the lines to the compressor, the overload opens the normally closed contacts in line 12, breaking the circuit to the CC. When the CC is de-energized, it opens its contacts in lines 1–3, breaking all the power to the compressor. Many commercial systems use lockout relays to keep the system from starting again after a safety has tripped. Figure 39-46 has a lockout relay in lines 12 and 13.

39.22 LOCKOUT RELAY

Many safety devices automatically reset after the condition that caused them to open has cleared. A system with an auto-resetting high-pressure switch is a good example. When the pressure switch shuts off the control circuit to the compressor, the pressure in the system will usually fall back down to a pressure that will allow the pressure switch to close again. The system will restart, and the high-pressure switch will trip again. The system will cycle on and off on the safety control, which can be almost as bad for the system as the original issue. A lockout relay prevents the system from restarting after a safety has opened until the control circuit is reset, preventing the system from cycling on and off due to a safety.

Lines 12 and 13 of Figure 39-46 show a lockout relay circuit. Notice that lockout relay coil will not be energized in normal operation because the string of safety controls effectively short the coil out of the circuit. There is no potential difference from one side of the lockout relay coil to the other (Figure 39-47). If any of the safety controls open, a circuit is established with the lockout relay coil in series with the

Figure 39-47 Lockout relay with unit operating.

Figure 39-48 Lockout relay safety tripped.

CC (Figure 39-48). The lockout relay is a higher impedance coil than the CC, so it receives nearly all the voltage. Even though the circuit still passes through the CC, the voltage drop through the CC is not enough to keep the contactor energized. The lockout relay normally closed contacts open because the lockout relay coil is now energized (Figure 39-48). The lockout relay will remain energized and the CC de-energized even after the safety control closes because the lockout relay normally closed contacts are open, preventing the normal circuit from being reestablished. To reset the circuit, the control circuit must be turned off and back on.

UNIT 39—SUMMARY

The control system regulates the operation of all the system components. Understanding how a system's control system operates is crucial to troubleshooting. Control systems generally fall into two broad categories: two position and modulating. Two-position control systems operate by turning things off and on, like a light switch. Modulating controls provide levels between on and off, like a light dimmer. Types of control systems include electromechanical, pneumatic, electronic, and direct digital. Electromechanical systems use mechanical switches and relays. Pneumatic control systems are modulating systems that operate by varying the air pressure to dampers and valves. Electronic control systems are modulating systems that use varying dc voltage or current. Direct digital control systems use integrated microprocessors to intelligently control system operation. They normally communicate with each other via a data network that is similar to a computer network.

Control systems can be described as either open loop or closed loop. Open-loop systems do not affect the condition they are sensing. A control system that regulates system operation based on outdoor temperature is an example of an open-loop system. Closed-loop systems receive feedback to maintain setpoint. A furnace with an indoor thermostat that controls furnace operation based on the room temperature is an example of a closed-loop system.

System cycling describes the on-and-off operation of the equipment that occurs as the control system operates the

equipment to maintain the setpoint temperature. The difference between the minimum and maximum room temperature is called swing. Two-position controls with mechanical thermostats can have a swing as high as 5°F. They reduce the swing using heating and cooling anticipators. The digital thermostats that are used today in place of mechanical thermostats have far less swing, usually less than a degree. They use more accurate temperature sensing and logic to reduce temperature swing. Proportional systems typically have less swing than two-position systems. Swing is caused by system overshoot and lag. Overshoot is delivering heating or cooling past the setpoint. Lag is a delay between the call for heating or cooling and the delivery of conditioned air.

WORK ORDERS

Service Ticket 3901

Customer Complaint: Unit Running but Not Cooling

Equipment Type: R-22 Commercial Packaged Air Conditioner

Diagram: Figure 39-46

A technician is called to look at a system that is not cooling properly. When he arrives the compressor is off, but both condenser fans are running. The compressor does not try to come back on. The technician looks at the diagram and notices that the compressor is protected by three overloads, a high-pressure switch, and a low-pressure switch in series with the contactor coil. He also notices a lockout relay keeps the system from starting again after a safety trips. The technician checks the voltage drop across each safety, reading 0 V across the high-pressure switch, the low-pressure switch, and all three overloads. He reads 230 V across the LR normally closed contacts, indicating that the lockout relay is keeping the system off. He installs gauges to help determine which safety is tripping and notices that the standing system pressure appears normal. He removes the red wire from the R terminal to reset the lockout relay, places a clamp-on meter around one of the three wires to the compressor, and touches the red wire to the terminal block to restart the system. The compressor hums but does not start, and the amp reading is very high. The tech disconnects power to the unit, removes the wires from the compressor, and ohms the compressor motor. One of the three terminals reads open to the other two, indicating a bad compressor motor.

Service Ticket 3902

Customer Complaint: Furnace Fan Operates Constantly

Equipment Type: Standing Pilot Gas Furnace

Diagram: Figure 39-20

A technician is called to look at a standing pilot furnace whose fan is running constantly. The diagram shows that the fan is controlled by both a fan relay and a fan switch.

The technician checks the current of the high-speed fan wire and finds 0 A. The amp draw of the low-speed fan wire reads 3.5 A, indicating that the fan is operating on low speed. The technician checks the settings on the fan switch, turns off the power to the furnace, and checks the continuity of the fan switch. It reads 0 Ω , indicating that it is closed even though the furnace is not hot. The fan switch is replaced and the fan quits operating all the time.

Service Ticket 3903

Customer Complaint: Poor Cooling

Equipment Type: Air-Source Heat Pump

Diagram: Figure 39-34

A technician is called to look at a heat pump that is not cooling well and notices that the outdoor fan is not operating. Consulting the diagram, the technician sees that the outdoor fan motor is controlled by the normally open C contacts and the normally closed DR contacts. A voltage measurement across the C contacts reads 0 V, while a voltage reading across the DR contacts reads 230 V. This reveals that the DR normally closed contacts are open. The technician suspects a faulty defrost board but does further checks to make sure. The diagram indicates that the defrost board is only energized in heating. He checks the voltage at the defrost control between B and common and reads 0 V. Finally he removes the defrost thermostat wires from the board and ohms out the defrost thermostat. It ohms OL, showing that it is open. The technician concludes that the defrost board is indeed bad and replaces it. After replacing the defrost board, the outdoor fan operates normally.

Service Ticket 3904

Customer Complaint: Unit Blows Cold Air in Heating

Equipment Type: Air-Source Heat Pump

Diagram: Figure 39-34

A service technician is called to look at an air-source heat pump that is blowing very cold air during the heating season. He checks the thermostat to ensure that the thermostat is calling for heat and is set correctly. At the outdoor unit, the technician notices that the gas line is cold, indicating the unit is operating in cooling. He checks the diagram and sees the reversing valve is energized in cooling by the O terminal of the thermostat. A voltage measurement at the reversing valve solenoid reads 24 V, indicating that the reversing valve is being energized even though the thermostat is set to heat. Examining the diagram further, the technician also notices that the defrost board can also energize the reversing-valve solenoid. He removes the orange wire from the O terminal and the reversing valve shifts, indicating that the problem is in the thermostat or control wiring. Back inside, the

technician removes the thermostat cover to check the control wiring. Everything appears to be wired correctly, but he notices an O B selector switch that determines when the O terminal receives power. It is set to B. He moves the switch to O, replaces the thermostat cover, and turns the system back on. The system operates in heat, and warm air starts coming out of the registers.

Service Ticket 3905

Customer Complaint: Compressor Short-Cycles

Equipment Type: Walk-in Cooler with Pump-Down Circuit

Diagram: Figure 39-16

A technician is called to look at a walk-in cooler whose compressor runs for a minute, remains off for about a minute, and then comes back on. The box temperature is close to the thermostat setpoint, but the customer is concerned about the compressor constantly cycling on and off. The customer confides that he adjusted the differential on the low-pressure switch from 20 psi to 5 psi, thinking it would make the cooler operate at a lower temperature. The technician explains that the differential setting is now so low that the slight pressure rise that occurs naturally after the compressor shuts off is closing the switch before it should. The switch is set back to the correct setting and the compressor stops short-cycling.

UNIT 39—REVIEW QUESTIONS

- What is the difference between an open-loop and a closed-loop control systems?
- What is the difference between a two-position control and a modulating control?
- List the types of control systems.
- How does a pneumatic control system operate?
- What is the difference between an electronic control system and a direct digital control system?
- Why are electromechanical control systems often referred to as relay control systems?
- Why is there a potential of 24 V between the R terminal and the other terminals on a thermostat sub-base?
- In Figure 39-34, what is the difference between emergency heat operation and normal second-stage heat operation?
- In Figure 39-34, what happens when the defrost relay (DR) is energized?
- In Figure 39-46, list the sequence of events that occur when the cooling relay is energized.
- In Figure 39-46, what determines whether outdoor fan motor 2 (OFM2) operates?
- In Figure 39-45, what does the LPS control?
- In Figure 39-34, when is the reversing valve energized: the heating cycle or the cooling cycle?
- In Figure 39-46, how does the high-pressure switch (HPS) protect the compressor?
- In Figure 39-24, what will happen if the limit switch opens while the furnace is operating?
- In Figure 39-34, what does the field control wire on the thermostat B terminal connect to on the unit?
- In Figure 39-46, how does the thermostat control the operation of the compressor?
- In Figure 39-33, what voltage operates the potential start relay coil?
- In Figure 39-33, what is the purpose of the potential start relay?
- List the heating operational sequence for the unit in Figure 39-25.
- In Figure 39-24, what controls the fan operation in heating?
- List the operational sequence for Figure 39-24.
- List the operational sequence for the second stage of Figure 39-34. Just list what happens when the W2 terminal is energized.

UNIT 40

Communicating Control Systems

OBJECTIVES

After completing this unit, you will be able to:

1. describe the basic operating concept of a communicating control system.
2. explain the difference between relay controls and communicating controls.
3. discuss the benefits of communicating control systems.
4. list the basic components of a communicating control system.
5. list common communicating system protocols
6. explain how to install a communicating control system.
7. discuss service procedures for communicating controls.

40.1 INTRODUCTION

Regardless of the equipment brand your company sells and services, every technician today needs to understand communicating controls. Just a few years ago, there were not many choices if you wanted a residential communicating system. Today, most major equipment manufacturers offer residential communicating control systems. Communicating systems used to be proprietary, but now there is an open standard to encourage the development of interoperable communicating equipment. The increasing popularity of communicating systems lies in their ability to improve overall system efficiency and improve comfort. The system components can communicate with each other and adjust system operation to match the heat load and operating conditions.

40.2 COMMUNICATING SYSTEMS VERSUS RELAY SYSTEMS

Standard air-conditioning control systems use relay logic or an electronic representation of relay logic. Things are either off or on. These controls work something like a light switch: when the switch is on, the light operates; when the switch is off, the light is off. Thermostats are basically switches that are controlled by temperature. The thermostat closes a set of contacts to complete a circuit to a relay coil, and the relay coil then closes the relay contacts to complete a circuit to a motor. When the thermostat is satisfied, its contacts open, breaking the circuit to the relay coil. The relay opens its contacts, breaking the circuit to the motor. Everything works based on the presence or absence of control voltage. Relay logic control systems have been the basis for HVACR controls for many years. However, this control system needs a separate control wire for each function. Some split-system heat pumps require ten control wires running between the indoor and outdoor section (Figure 40-1). Even with ten wires, the range of control is still somewhat limited. Relay systems cannot use operating data and logic to make control decisions, but communicating systems can.

A communicating control system is more like a computer network. The main controller can be compared to the computer in a home network. The other communicating components are the peripherals connected to the computer. In a communicating control system, the system components communicate over a serial network. Each part has its own unique electronic signature or address, allowing the controller to recognize all the parts and coordinate their operation. Most residential communicating systems use four wires between all components—two for power and two for communication. It does not matter if the component is a furnace, air handler, air conditioner, heat pump, or zone control—everything uses the same four-wire connection (Figure 40-2). This works because the units respond to commands sent over the communication network, not the presence or absence of control voltage. Commands for different components can be sent over the same network, and communication is not just one

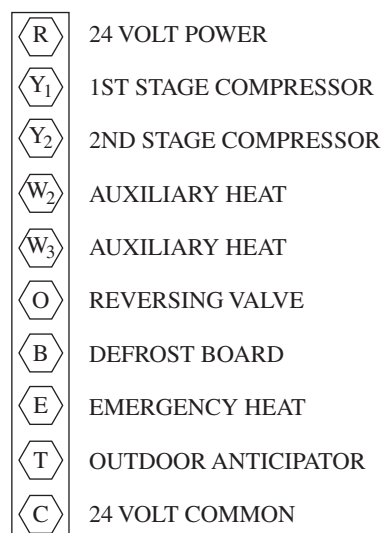

Figure 40-1 Typical control wire terminal board for a two-stage heat pump system using 24-volt controls.

Figure 40-2 Four-wire communicating control system.

way. Communication between components allows each component to know what the other components are doing and adjust accordingly. For example, a communicating zone control knows the total blower airflow in cubic feet per minute (CFM) and the CFM in each zone. Better yet, it can report this to the service technician (Figure 40-3). The system airflow can be ramped up or down to match system capacity. Staged furnaces, air conditioners, and heat pumps give the system the ability to modulate system capacity and airflow as the house load requires, improving efficiency and reducing energy use.

Figure 40-3 Communicating zone controls know how much air the fan is moving and the static pressure it is working against.

40.3 COMMUNICATING APPLICATIONS

Communicating controls are used in a wide range of applications, including ductless mini-split systems, multistage air conditioners and heat pumps, multistage furnaces, multistage split-system air conditioners and heat pumps, water-source heat pumps, and zone control systems. Any application that uses multistage or modulating technology can benefit from communicating controls. Communicating controls can send commands and information over the same network, allowing complex control with just a few wires. Communication makes monitoring and controlling variable-capacity systems much easier. The components send information about their status and operating conditions to the controller, giving the controller real-time information on system operation. Manufacturers are offering more variable-capacity systems because of their increased efficiency. Most of these systems use communicating controls.

Zoning is a strong application for communicating controls. Mini-split systems with multiple indoor coils use communicating controls to match system capacity to the building load using variable refrigerant velocity. These systems have multiple indoor coils connected to a single outdoor condensing unit that has a variable speed compressor. The communicating control system allows the unit to match its capacity to the combined required capacity of the multiple indoor units (Figure 40-4). Communicating zone controls for ducted systems are also available (Figure 40-5). Communication makes it possible for the variable-capacity equipment to match its output to the demand from the different zones. Airflow is also regulated based on the number and size of the operating zones.

Figure 40-4 Mini-split VRV multiple-blower system.

Figure 40-5 Communicating zone control.

GREEN TIP

Communicating variable-refrigerant-velocity mini-split systems can save energy by matching the equipment capacity to the demand. They can also shift capacity from one side of a building to another as the load dictates. This allows for less overall installed capacity and lower energy use without sacrificing comfort.

40.4 HOW COMMUNICATING CONTROLS WORK

Communicating controls send messages over a serial network that is very similar to a computer network. Each communicating component contains a small microprocessor, an electronic address that tells the other components in the network what it is, and the electronics necessary for it to respond to the commands it receives. Communication is accomplished through a series of voltage pulses that represent digital commands and data (Figure 40-6). These pulses are carried over two wires that form a communication bus. The communication bus connects all the communicating components in parallel. Commands sent over the bus are received by all the components. The components simply ignore commands and data that are not addressed to them. This is why communicating systems can accomplish more with four wires than traditional relay logic systems can with twelve wires. With traditional relay logic, each wire can only perform one function. The wires that form the communication bus can deliver commands to all the system's communicating components over the same two-wire communicating bus. Hundreds of commands can be sent over the same two wires.

Figure 40-6 Diagram of pulses used to communicate over a communicating network.

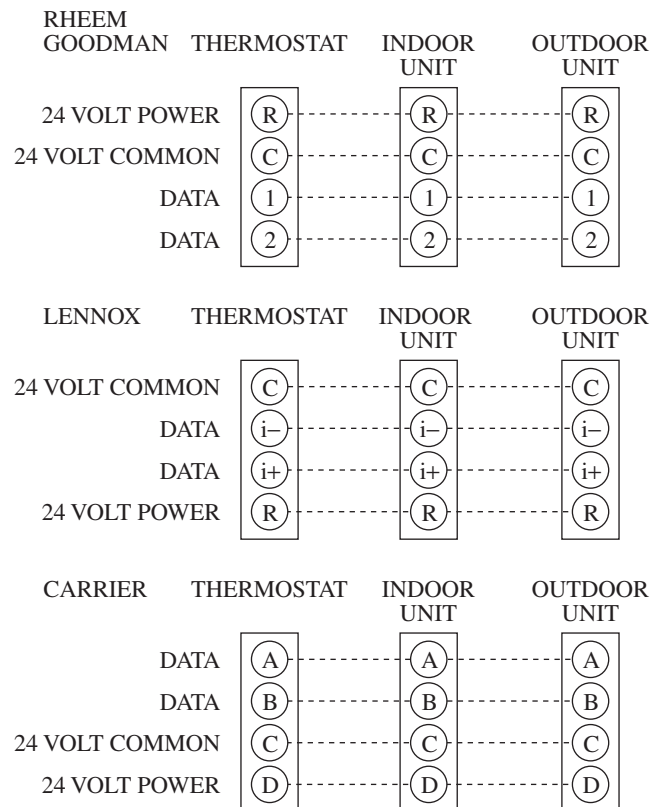

Figure 40-7 Four-wire communicating connections for several manufacturers.

Components are wired to each other using two to four wires, with four wires being the most common. A four-wire connection uses two wires dedicated to control power and two wires strictly for communication (Figure 40-7). Two- and three-wire systems either are powered through the component's primary power source or perform double duty as both a power source and a communication bus (Figure 40-8).

40.5 COMMUNICATING PROTOCOLS

All communicating systems follow some type of protocol. A protocol is an agreed standard set of rules that are used for communication on a network. Proprietary systems follow

Figure 40-8 Communicating system using a two-wire connection to outdoor unit.

their own unique protocol, which is licensed and controlled by the manufacturer. An open protocol is available to all manufacturers. Open protocols establish rules that are followed by multiple manufacturers so that their systems can communicate with each other, allowing pieces of equipment from different manufacturers to operate as a single intelligent system.

In the early years of commercial direct digital control (DDC) building-automation systems, a large commercial building could have control systems from multiple manufacturers that could not communicate with each other. Individually, each system might have represented the most advanced control for its market segment, but collectively they fell short of their promise because they could not operate as a coordinated system.

Interoperability is the ability of pieces of equipment from different manufacturers to communicate with each other and operate as a single communicating system. Components that follow a standard protocol can work with each other. In building automation, this extends beyond different air-conditioning manufacturers. Intelligent utility interfaces, lighting, fire alarms, security, and HVACR can all tie together, creating an intelligent building automation system where all the components can communicate and optimize their operation based on data from each other (Figure 40-9).

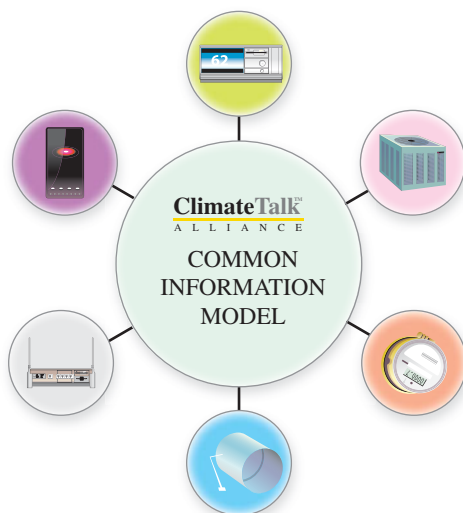

Figure 40-9 ClimateTalk communicating control systems can integrate several types of products with a single system. (ClimateTalk™ Information Model word mark and artwork are used with the permission of the ClimateTalk Alliance.)

BACnet Protocol

Although communicating controls are relatively new in the residential market, communicating controls have been common in commercial HVACR for many years. Communicating commercial controls are often referred to as direct digital controls, or DDC. Commercial DDC controls are used for building automation, not just air-conditioning systems.

A building-automation control network standard was developed to help develop the building-automation control industry by promoting interoperability. Interoperability means that components and equipment from different manufacturers can communicate with each other and work together. The availability of “standard” communicating components and an open protocol means that more manufacturers can use communicating controls, opening the market up. BACnet demonstrated this at the 1996 ASHRAE show in Atlanta, when multiple controllers from several major manufacturers were up and operating, all connected to the same BACnet system. The BACnet standard for building automation was published in 1995 and updated in 2001. It was adopted in 2003 as an ISO standard. Today all major manufacturers of large commercial air-conditioning equipment offer BACnet-capable systems.

Climate Talk Protocol

BACnet is primarily a commercial standard. ClimateTalk is an open standard designed to encourage the development of residential communicating equipment. ClimateTalk is a much younger protocol, introduced in 2009. The ClimateTalk Alliance is an organization of companies who are committed to developing a common communication infrastructure for HVAC and smart grid devices, enabling the interoperability of diverse systems. Available ClimateTalk controls include thermostats, furnace control boards, air-conditioning and heat pump control boards, and variable-speed brushless dc motors. Several manufacturers are offering ClimateTalk-capable equipment, including furnaces, air conditioners, and heat pumps.

40.6 COMMUNICATING CONTROL SYSTEM COMPONENTS

The basic communicating control system includes a main controller, a board to control the furnace or heat pump air handler, and a board to control the condensing unit. Many electronically controlled brushless dc variable-speed motors can also send and respond to commands through the communicating control network. System accessories such as zone controls, humidifiers, and air cleaners can connect with the communicating control system for a complete comfort solution that responds intelligently to operating conditions.

TECH TIP

Some manufacturers refer to the component that replaces the thermostat as a communicating thermostat, while others refer to it as a communicating control.

Figure 40-10 Communicating touchscreen thermostat.

Main System Control or Thermostat

The main controller looks like a digital thermostat (Figure 40-10). Like a thermostat, the main controller is responsible for coordinating overall system operation. However, the controller is far more sophisticated. Typically, a single controller model is used for all types of systems, including furnaces and air conditioners, heat pumps, or dual-fuel heat pumps. The controller looks to see what is connected to the network and modifies its operation to fit the system components connected to the network. It not only controls when equipment operates, but it also manages the communication network, controls system capacity to match the load, records system fault history, and provides service data and information to the technician. While thermostats are basically switches, communicating controllers are intelligent and make decisions based on their programming and the information they receive from the rest of the system.

Furnace Control Board

Communicating furnaces are typically multistage or variable capacity. Overall system efficiency is increased by matching the furnace heating capacity to the heat load. Their ability to produce different levels of heat reduces the amount of fuel burned and extends the furnace run time. The furnace board communicates the current furnace status and operating data to the system controller. The board on the furnace is responsible for receiving commands from the controller and coordinating operation of the furnace to produce the level of heat called for by the controller (Figure 40-11). Different firing rates are accomplished by controlling the speed of the combustion air blower and the different stages of the gas valve. Communicating furnaces usually have variable-speed blower motors. The furnace control adjusts the blower speed to match the heat output of the furnace. This ensures that the delivered air stays warm even at reduced firing rates.

Air-Handler Control

Communicating heat pump air handlers and blower coils use variable-speed indoor blowers. The air-handler communicating board controls the indoor blower speed to match the system capacity (Figure 40-12). When the system controller operates the system at reduced capacity, the

Figure 40-11 Communicating furnace board.

variable-speed indoor blower also runs slower. This ensures cool air in the cooling cycle and warm air in the heating cycle even at reduced capacity. Many communicating controllers can also control indoor humidity. They can reduce the indoor blower speed during the cooling cycle to increase latent cooling for dehumidification.

Figure 40-12 Communicating blower board.

Figure 40-13 Communicating condensing unit board.

Condensing Unit Controls

Communicating air conditioners and heat pumps typically have two-stage or variable-capacity control. The ability to operate at reduced capacity allows them to operate using less electricity and operate with longer running times. This increases both efficiency and comfort. The condensing unit board controls compressor operation, including staging (Figure 40-13). On heat pump condensing units, the communicating board also controls the defrost cycle. The condensing unit control communicates the condensing unit operating data to the main controller inside, including which stage the compressor is operating in, the outdoor temperature, and information for the defrost cycle on heat pump boards.

Accessories

System accessories can also tie into the communicating network. Zoning boards, humidifiers, and air cleaners are all

available for integration in communicating control system (Figure 40-14). Information from the system indoor blower helps all these components perform their jobs better. Communicating controls allow accessories to tailor their operation to the system operation.

40.7 EXTERNAL COMMUNICATION

Communicating systems can also communicate with devices and networks outside of the HVACR network. Most communicating control systems have the ability to connect to the Internet, allowing remote system monitoring and control. Homeowners can “check in” on their HVACR systems while they are away and even change system set points. Internet communication can be done through a traditional Web-connected computer, a wireless laptop, or even a smart phone. Usually, a separate component is added to the system to handle communication with the Internet. However, there are thermostats that are designed to be connected directly to a computer network via a Cat5 Ethernet connection or even a wireless router (Figure 40-15).

40.8 WIRING A COMMUNICATING SYSTEM

Reading the manufacturer’s literature and instructions is always important when installing HVACR equipment. With communicating systems, it is an absolute necessity. Even though there are just a few wires, it is still possible to connect them incorrectly. The time spent studying the system and its specific installation instructions before installation will save time after installation by reducing problems.

In addition to the connections for the communicating controls, most communicating furnaces and condensing units have connections for standard 24-volt thermostat control as well as communicating control connections (Figure 40-16). These legacy connections allow the units to be used with standard 24-volt thermostats. However, the system cannot deliver all the benefits of communicating

Figure 40-14 Communicating zone board.

Figure 40-15 This Wi-Fi thermostat can communicate via 802.11b/g wireless.

Figure 40-16 This communicating control board has both legacy and communicating connections.

control when connected using the standard 24-volt controls. It is important for the installer to understand that either the legacy 24-volt connections or the communicating connections should be wired, but not both.

SERVICE TIP

Do not connect both the terminals for the legacy controls and the terminals for the communicating controls. If you are wiring a communicating system, you do not need the standard terminal connections on the control.

Figure 40-17 Typical connection problems from left to right: red wire missing middle of connector clamp; doubling wires in connector; leaving bare wire past the connector.

Although good connections are crucial for any control system, good electrical connections are even more important with communicating systems. Connections that would work with common relay controls will intermittently fail with communicating systems. Some specific pitfalls to avoid are stranded wires, incorrectly stripped wires, wires improperly placed in the connector, and multiple wires in the same connector (Figure 40-17).

Four-Wire Systems

The most common communicating control systems use four wires to connect the system components. Two wires carry the control voltage and two more wires provide the communication bus. Standard 18-gauge solid thermostat wire is used. Each component uses the same four connections, making connections very easy. The four connections are labeled the same on each control board. Although there are only four wires, it is important not to get the connections confused. The polarity of the power wires needs to be observed. Normally, polarity is not an issue with two wire AC control systems, but it is important with communicating systems. Figure 40-7 shows the wiring for several types of four-wire systems.

Although each communicating board uses four wires, the control board at the furnace or heat pump air handler must connect to two sets of four-wire bundles: one set going to the main controller (the thermostat), and one set going outside to the condensing unit. Some early communicating boards on furnaces and air handlers only had one set of connecting blocks. Although it seems logical to put one wire from each bundle in the connection, this is wrong. Placing multiple wires in the same connector leads to erratic communication problems. To solve this problem, connect a short wire, called a pigtail, to the connector. Then connect the pigtail to one wire from each bundle using small orange wire nuts. This has a decidedly low-tech look for an advanced communicating control system, but it works. Just be careful to make good wire nut connections.

Two-Wire Systems

Four-wire systems still have two more wires than are commonly used for standard air-conditioning condensing units. Two-wire communicating systems make it possible to replace a standard air-conditioning system with a communicating system without pulling new control wires. Some systems use two wires between the furnace or air handler and the outdoor condensing unit, allowing the use of 18-2 thermostat control wire to the condensing unit. The outdoor unit has its own transformer, making it unnecessary to run control power from inside to outside. The two control

wires are common and data. It is important not to cross-connect the wires. Although there are only two wires, it is still possible to connect them incorrectly. These systems typically use three or four wires between the furnace or air handler and the comfort control. Figure 40-8 shows the wiring for different types of two-wire systems.

40.9 INITIAL SYSTEM SETUP

When the main controller is first powered up, it searches the network to identify all the components connected to it. Typically, the controller displays what it has found and gives the installer some setup options (Figure 40-18). Many controllers can remind the owner when it is time to change the air filter or perform seasonal service. Dealer contact information can also be programmed in so that it is displayed in service reminders. This type of information is typically entered by the installing technician as part of the system setup.

The controller remembers the equipment connected to the network. In the event that the controller loses power, it will not have to reconfigure when it is powered on. It will simply try to communicate with the equipment it expects to see. If system components are changed, the controller will need to relearn the system. It may give communication errors because it will still be looking for the component that was replaced (Figure 40-19). To solve this issue, go into the service screens. From there you can instruct the controller to rescan the system; it will perform the same network scan that it normally does on initial system power-up. This is similar to rebooting a computer. Remember that a communicating network is essentially a computer network. The controller (thermostat) is the main computer and the units are the peripherals. Unlike computers that automatically detect new components, communicating systems must be told to look for them. The system must be rescanned if new

Figure 40-18 After scanning the system, the control displays the components it found on the network.

Figure 40-19 The screen indicates a communication error. The communication LED on the furnace board is out, indicating that the unit is not communicating.

communicating components are added to an existing communicating system.

40.10 INSTALLATION AND SERVICE SCREENS

The main controller (thermostat) has installation and service screens to help configure, install, and service the system. These screens typically require key presses or key sequences that are not in the owner's manual provided to the customers. Current system components and their status can be viewed on the main controller in the service screens. Technicians can view the system fault history from the service screens (Figure 40-20). Because the system components communicate with the controller, faults of all connected components can be viewed, not just controller faults. System settings and configuration can also

Figure 40-20 The unit's fault history can be displayed on the screen.

Figure 40-21 The top configuration screen is alphanumeric. The bottom one uses number codes.

be changed at the service screens. System configuration varies from an alphanumeric code to a short text message (Figure 40-21). You really need the manufacturer's literature to configure any of these systems, but the systems that use text prompts are definitely easier to set up.

SERVICE TIP

The key presses or touches required to access the service screens on the controller are not published in the user's manual. They are typically only published in the manufacturer's service literature.

40.11 ACCESSING THE INSTALLATION AND SERVICE SCREENS

A lot of valuable service information is available through the controller if you know how to access it. Each system has its own secret combination that unlocks this valuable information.

Amana and Goodman ComfortNet

Figure 40-22 shows a ComfortNet communicating thermostat used for controlling Amana and Goodman ComfortNet products. To view the advanced installer configuration menu, press the Menu button on the bottom right of the touchscreen. A new screen will appear with selections along the bottom. Press and hold the Installer Config button for three seconds. The screen will change. Press and hold the Installer Config button again for three seconds. The screen will change once more and the word *Advanced* will

Figure 40-22 Touchscreen communicating thermostat.

appear in the bottom right corner. Figure 40-23 shows this sequence of settings and screens. Any faults will be displayed. You can scroll through the faults using the right and left arrow keys at the top left of the screen. Pressing either of the up or down arrow keys on the right will take you back to the user menu.

Carrier Infinity and Bryant Evolution

Figure 40-24 shows an Infinity communicating controller for Carrier and Bryant communicating products. Carrier's Infinity systems and Bryant's Evolution series are compatible. To view the service screens, press and hold the "advanced" button for ten seconds. The install/service menu will appear. Use the scroll button to scroll down to Service at the bottom of the list. Press the Select button on the right side of the control to display the service screen. Figure 40-25 shows this sequence of settings and screens. You can view the status of any installed equipment and view the system fault history from this screen.

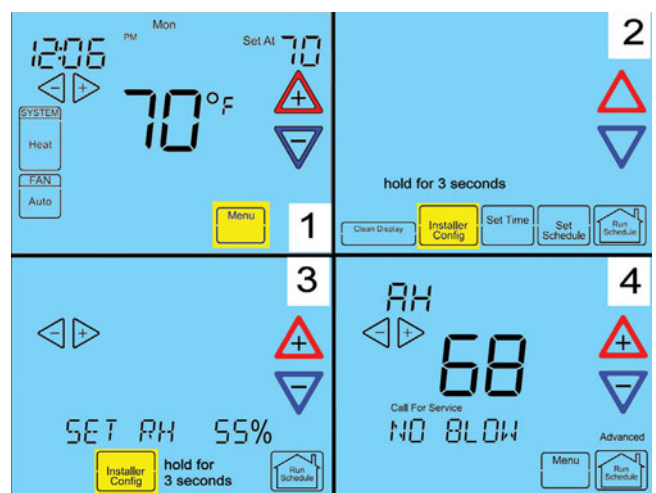

Figure 40-23 Steps to display the service screen on ComfortNet communicating thermostats.

Figure 40-24 Infinity control.

Lennox icomfort

Figure 40-26 shows an icomfort thermostat used to control Lennox icomfort communicating products. The screens are arranged similar to a tabbed browser. Critical alerts are displayed both on the home (user) screen and in the installer screen. Press the Alert tab to view current critical

Figure 40-25 Steps to display the service screen on Infinity control.

Figure 40-26 Lennox icomfort communicating thermostat.

Figure 40-27 Push and hold the Lennox Logo for five seconds to enter the service screen.

alerts. Minor and moderate alerts are found only in the Installer Alert tab. To access the Installer menu, press the Lennox logo in the bottom right corner of the screen for five seconds (Figure 40-27). A warning will appear: “The following screens are intended for use by qualified Lennox equipment installers only.” Press Yes to continue. Press the Diagnostics tab to run diagnostic tests on connected equipment, or press the Alerts tab to view system fault history and current faults.

Rheem and Ruud Comfort Control

Figure 40-28 shows a Comfort Control thermostat used with Rheem and Ruud Comfort Control communicating products. To view the advanced installer menu, press the left and right buttons simultaneously for three seconds (Figure 40-29). The up and down arrows are used to scroll through the options. Options include Communicating Devices, Heat Pump Disable, Fault Status, Air Handler Lockout, USB Upload, Dual Fuel Setpoint, Thermostat Summary, Heat Cycle Rate, De-Hum Setpoint, Cool Cycle Rate, and Humidity Setpoint. Go

Figure 40-28 Rheem Comfort Control communicating thermostat.

Figure 40-29 Push and hold the two arrow keys simultaneously to go to the service screen.

to Communicating Devices to see details of specific connected devices. Go to Fault Status to read the fault history.

Trane ComfortLink II and American Standard AccuLink

Figure 40-30 shows an XL900 communicating thermostat for Trane ComfortLink II communicating products. Trane ComfortLink II products are compatible with American

Figure 40-30 Trane XL 900 communicating thermostat.

Figure 40-31 From top down: Touch the System button. The screen changes to the second screen. Press and hold the two blank buttons on either side of the middle button for five seconds. The screen changes to the bottom configuration screen.

Standard AccuLink communicating products. To view the Advanced Setup menu, press and release the System button on the middle left of the touchscreen. A row of blank buttons will appear at the bottom of the screen. Press and hold the two blank keys on either side of the center blank key for approximately five seconds until the screen changes, then press and hold the Installer Config button again for three seconds. The screen will change once more, and the word *Advanced* will appear in the bottom right corner. Figure 40-31 shows this sequence of settings and screens. Any faults will be displayed. You can scroll through the faults using the right and left arrow keys at the top left of the screen. Pressing either of the up or down arrow keys on the right will take you back to the user menu.

40.11 TROUBLESHOOTING THE SYSTEM

A big advantage of communicating systems is that they can save and display a fault history for all the connected components, so service technicians can see what has been happening with the system. The first step in troubleshooting a system with communicating controls should be to go

Figure 40-32 Fault screen showing repeated low-pressure-switch fault (lps).

to the service screen. There you can see the components connected to the system and check the current status of each component. Current faults are displayed so that you can see what is currently happening. It is also useful to check the fault history. For example, a system that has repeatedly tripped out on the low-pressure switch will show that on the service history (Figure 40-32). Even if the system is not currently tripped out on low pressure, you can see that it has tripped out on low pressure before. Seeing this, you can look for problems associated with low pressure. After addressing the issue, you can clear the fault history if you want to record only faults that have occurred since your most recent visit.

40.11 TROUBLESHOOTING COMMUNICATION ERRORS

The fault may not be in the operation of a particular component but in communication between components. This will normally show as a communication error on the service screen. The most common error message says, “Communication error with...” and then lists the equipment that it expects to see with which it cannot communicate (see Figure 40-19). This may be a problem with the control or the equipment, but it can also be something simple, such as a loss of power to the equipment or a loose connection.

Check Settings and Power

Like any system, the first step is to make sure the thermostat, or control, is set to call for the system to operate. Some customers are confused by the extra information and touchscreen controls often used with communicating systems and literally do not know how to turn the system

on. Customers who are not comfortable with personal electronics may need a little extra time to learn the operation of their system.

SERVICE TIP

Not all customers are tech savvy and may be intimidated by touchscreens and electronics in general. Try to avoid “tech speak” when showing customers how to operate their system.

After establishing that the control is calling for the unit to operate but the system is not operating, you will need to troubleshoot the control system. Again, start with simple checks. Does the equipment have the correct line voltage? Just like relay systems, communicating systems will not operate if they don’t have power.

Check Fault Lights and Displays

Communicating control boards have fault lights or displays that show the status of the system. Boards with fault lights often have a light dedicated to indicating communication status (Figure 40-33). This light will change color or flash to indicate that the board is not communicating. Some boards have displays that indicate the status of the system. In either case, checking these fault indicators is relatively easy to do and takes very little time. Checking them early in the troubleshooting process can save a lot of time.

Check Connections

Next, check the connections at the control and the unit. Poor connections are the most common cause of communication errors. Intermittent communication errors frequently can be traced back to the connections. Check these specific items:

- Make sure the correct wire is used—solid, 18-gauge copper.
- Make sure the wire is stripped to the correct length.

Figure 40-33 Communication light on board.

- Do not put multiple wires in the same connector.
- Be sure the wires are not reversed between the control and the unit

Occasionally wires break inside the plastic insulating jacket with the insulation remaining intact. Check near the end of the wire for awkward-looking sharp turns in the wire. You can check for wires with breaks using an ohm meter. Remove the wires from the connectors on both sides, twist two wires at a time together on one end, and ohm out the other end. A reading of a few tenths of an ohm indicates that the wires are OK. If either wire has a break, the reading will be infinite. If any of the wires have a break, you should pull a new set of control wires. This usually takes less time than trying to locate the break. Frequently if one wire is damaged, others are also.

40.12 WIRELESS CONTROLS

Not all communicating controls use wires. Wireless communicating controls use radio signals for interconnection and communication between components. A wireless thermostat can be easily installed in locations that a wired thermostat cannot be installed since they are not limited to locations where wires can be routed. This is especially helpful in renovation and retrofit applications. Currently, wireless systems still must have an interface to translate signals from the wireless system to the air-conditioning components because no air-conditioning systems are currently available with wireless controllers built in. The interface wires into a traditional 24-volt relay control system, allowing the wireless thermostat to control the system. Using wireless systems for zone control makes zone thermostat location easier. This is especially true for a retrofit zoning application. Wireless thermostats can connect to the Internet through a wireless router, similar to a laptop or game console.

UNIT 40—SUMMARY

Standard relay logic air-conditioning control systems work something like a light switch: when the switch is on, the light operates; when the switch is off, the light is off. Everything works based on the presence or absence of control voltage. In a communicating control system, the system components communicate over a serial network. Units respond to commands sent over the communication network, not the presence or absence of control voltage. Communication between components allows each component to know what the other components are doing and adjust to match the operating conditions. The language systems use for communication over a network is called a protocol. Two well-known communicating protocols are BACnet for commercial systems and ClimateTalk for residential systems. The increasing popularity of communicating systems lies in their ability to improve overall system efficiency and improve comfort by matching the system capacity to the heat load. The basic communicating con-

trol system includes a main controller, a board to control the furnace or heat pump air handler, and a board to control the condensing unit. Most residential communicating systems use four wires between all components—two for power and two for communication. It does not matter if the component is a furnace, air handler, air conditioner, heat pump, or zone control—everything uses the same four-wire connection. Communicating systems record the system fault history, allowing service technicians to view the problems that have occurred in each of the system components. Fault histories are viewed on service screens on the communicating controller or thermostat. Faults in communication as well as faults in individual components are reported on the service screens. The manufacturer's instructions are critical for understanding and servicing communicating systems. Most communication problems are the result of bad connections.

WORK ORDERS

Service Ticket 4001

Customer Complaint: Unit Not Cooling

Equipment: Four-Wire Communicating System with Furnace and Air Conditioner

A technician is called to look at a communicating system that is not cooling properly. He goes first to the thermostat to check the service screen. The system status screen shows that the condensing unit is off. The fault history shows several low-pressure events. The technician selects the OFF mode on the touchscreen and goes outside to check the system pressure. The equalized pressures look reasonable. He turns off power to the system, disconnects the low-pressure switch, and ohms it out. The reading is OL, indicating that the switch is open even though the equalized pressure is above the cut-out point. The technician determines that the low-pressure switch will have to be replaced.

Service Ticket 4002

Customer Complaint: Unit Not Communicating

Equipment: Four-Wire Communicating Heat Pump Split System

A technician is called to start a new communicating heat pump. On the initial system scan, the control finds the indoor blower but not the outdoor unit. The technician goes to the indoor blower to inspect the connections on the blower board. She finds that the wires to the thermostat and the outdoor unit have both been placed in the same connection because the board only has one set of communicating connections. She removes the wires from the connection block, installs a single set of wires on the terminals, and then connects the thermostat and outdoor unit connections to the pigtail using wire nuts.

Returning to the thermostat, the technician enters the service screens and instructs the system to perform a new scan. This time the controller finds both the indoor and outdoor units.

Service Ticket 4003

Customer Complaint: Communication Error

Equipment: Four-Wire Communicating Variable-Capacity Furnace

A technician is called to start a new communicating furnace. A communication error is reported during the initial system scan. The technician goes to the furnace and checks the communication LED. It is not on. He turns off the power to the furnace, inspects the connections, and records the wire colors used. The connections appear to be fine, so he returns to the thermostat and removes it from the sub-base. While checking the connections he notices that the two wires on the data lines have been swapped between the thermostat and the unit. He swaps the wires at the thermostat and replaces the thermostat on the sub-base. After turning the power back on, the furnace communicating LED lights up. The technician returns to the thermostat, navigates to the service screen, and instructs the thermostat to rescan the system. This time the thermostat recognizes the furnace.

Service Ticket 4004

Customer Complaint: Wireless Thermostat Has Stopped Working

Equipment: Communicating System with Wireless Thermostat and Wireless Receiver

A customer calls because his wireless thermostat has stopped working. He replaced the batteries and it still does not work. The technician goes to the receiver and notices the LED that indicates the presence of a signal from the thermostat is not lit. Next, she goes to the thermostat. The display appears to be working. Even though the customer said he replaced the batteries, the technician removes them and checks the battery voltage. It is 1.45 volts DC. She explains that even though the batteries are rated at 1.5 volts, a good battery will normally read more than 1.5 volts new and with no load. The 1.45 reading indicates weak batteries. She explains that wireless thermostats are very affected by weak batteries because their signal is weakened. The customer says that he just put these in, but they came from the surplus discount center. The

technician replaces the batteries with new, high-quality, alkaline batteries. The thermostat now is able to turn on the air-conditioning system. The technician recommends that the customer only use high-quality, in-date alkaline batteries for his wireless thermostat.

UNIT 40—REVIEW QUESTIONS

1. What is a communicating control system?
2. Explain the difference between the way a relay logic control system operates and the way a communicating control system operates.
3. How can a two-stage heat pump be controlled by only four wires?
4. What is a communicating protocol?
5. List two open protocols.
6. What are the four wires used for in a common four-wire communicating system?
7. How do some communicating systems operate with only two wires between the indoor blower and the condensing unit?
8. Why do communicating control boards often have terminals for traditional 24-volt controls?
9. What type of wire should be used for connecting components of a communicating control system?
10. What is the cause of most communication errors?
11. How can a service technician learn what problems a communicating system has been experiencing?
12. Why is the manufacturer's installation and service literature critical when working with communicating systems?
13. How does a communicating thermostat know what type of equipment is connected to it?
14. What applications are wireless communicating thermostats particularly well suited for?
15. How do communicating components determine which commands are for them and which commands are for other devices connected to the network?
16. Why are communicating controls particularly well adapted for modulating capacity systems?
17. How can a technician force a system to scan the system and relearn the components connected to it?
18. Why are communicating controls particularly well adapted for zone control systems?
19. What type of zone control do some communicating ductless mini-split systems use?
20. Explain the concept of interoperability.
21. Discuss the difference between a proprietary system and an open system.

UNIT 41

Fundamentals of Psychrometrics and Airflow

OBJECTIVES

After completing this unit, you will be able to:

1. discuss the factors affecting human comfort.
2. list the ways the body dissipates heat.
3. explain the relationship between dry-bulb, wet-bulb, and dew-point temperatures.
4. plot points on the psychrometric chart given any two variables.
5. locate all unknown air properties on a psychrometric chart from the intersection of two known air properties.
6. calculate the mixed air temperature of two different temperature airstreams.
7. calculate CFM from velocity and area.
8. explain the difference between FPM measurements and CFM measurements.
9. explain the differences between static pressure and velocity pressure.

41.1 INTRODUCTION

Air properties and airflow are the heart of air conditioning. Technicians need to understand air properties and airflow to be able to troubleshoot and maintain an HVACR system. Factors that adversely affect system airflow will also have a negative impact on system efficiency and reliability. When people think about the properties of air and comfort, they think first about temperature. However, temperature is not the only property of air that is important to air conditioning. The properties of air include weight, volume, temperature, water content, and heat content. Humidity is nearly as important to human comfort as temperature. All the properties of air are important for the operation of air-conditioning equipment. The study of air and its properties is called psychrometrics.

41.2 CONDITIONS FOR COMFORT

Comfort is the feeling of physical contentment with the environment. The study of human comfort involves understanding how the area around a person affects the feeling of comfort and how the body adapts to changes in its environment. Many tests have been run to determine what conditions most people consider comfortable in the winter and the summer. The surrounding temperature, relative humidity, and air movement are all influencing factors. In the winter, cooler temperatures can be offset by higher relative humidity and less air movement. In the summer, higher temperatures can be offset by lower relative humidity and increased air movement.

Generalized Comfort Chart

The results of test data have been incorporated in comfort charts, one for summer conditions and one for winter

conditions. Figure 41-1 shows the summer comfort conditions in red and the winter comfort conditions in blue. Note that the temperature range for summer comfort is about 5°F higher than the winter temperature comfort range. This assumes the use of warmer clothing in the winter and lighter clothing in the summer.

Body Temperature Regulation

Normal internal human body temperature is 98.6°F, winter and summer. The proper functioning of the body is dependent on constantly maintaining this temperature. The body temperature of warm-blooded animals, including humans, is closely controlled by producing more internal heat than necessary and regulating the release of that heat to the surroundings. The heat is produced by converting food energy into heat. There are four ways the body loses heat to the environment:

- Conduction (Figure 41-2)
- Convection of cool air (Figure 41-3)
- Radiation (Figure 41-4)
- Evaporation (Figure 41-5)

Conduction, radiation, and convection all require surrounding conditions that are cooler than the body temperature to dissipate heat. Conduction cools the body by the transfer of heat from the skin to the air surrounding and touching us. Convection accelerates the cooling process by movement of cool air over the body, increasing the transfer of heat from the body to the air. The wind-chill effect often reported in the winter is due to convection. Cooling by radiation occurs when we get close to a large object that is colder than our body temperature. Heat loss through radiation can be demonstrated by standing next to a cold outside wall in the winter. Heat leaves the body and travels to the cold wall without the person actually touching the wall.

Figure 41-1 Generalized comfort conditions; summer conditions are shown in red and winter conditions are shown in blue.

Figure 41-1 (continued)

Figure 41-2 Heat is lost from the body by conduction to a film of air in contact with exposed skin.

Figure 41-3 Heat is lost from the body by convection of the air around the body.

The body cannot be cooled by conduction, convection, and radiation whenever the surrounding temperature is warmer than body temperature. In fact, these processes begin transferring heat in. Evaporation is the only body-cooling process that does not require cooler surroundings. Evaporation only requires that the body produce sweat and that the surrounding air be able to absorb water. Rapid evaporation of perspiration produces a cooling effect. This is why the humidity plays an important role in human comfort. People feel cooler in drier air because their perspiration can readily evaporate. They feel warmer in air with a higher relative humidity because the evaporation process is slower.

The body has a remarkable ability to adjust to temperature change. When a person goes from a warm house into the cold outdoors, some compensation needs to be made to prevent excessive heat loss. Involuntary shivering occurs, providing body heat. When a person goes from an air-conditioned space into an outside temperature of 95°F, an adjustment in the circulatory and respiratory system takes place. The blood vessels dilate to bring the blood closer to the surface of the skin to provide better cooling. If this is not enough, sweating occurs. The sweat evaporates from the skin, producing a large amount of body cooling.

Level of Activity

Comfort is also affected the level of physical activity. Active people feel more comfortable at cooler temperatures than

Figure 41-4 The body radiates heat to the surrounding surfaces/objects.

Figure 41-5 The body loses heat by evaporation of water from the skin.

sedentary people. This is because activity creates more body heat, requiring more cooling to maintain comfort. Figure 41-6 shows the comfort temperature ranges for different levels of activity.

TECH TIP

As people age, their circulation tends to decrease. For that reason, elderly residents will often complain about a chill even when the home's system is set well above the norm. One way to make the area more comfortable is to arrange supply-air diffusers so they do not blow into the occupied space. Air movement can cause a slight chill for these individuals even though the room is comfortably warm for the other occupants. It may be necessary to change out the supply-grille faces with longer, curved grille faces that are specifically designed for heat pump applications.

41.3 AIR WEIGHT AND VOLUME

Air has weight and takes up space. Atmospheric pressure is caused by the weight of the air. We are not aware of the air around us or the atmospheric pressure created by

Temperature		Comfortable Temperature Levels for Different Activities
°F	°C	
78	25	Optimal for bathing, showering. Sleep is disturbed.
75	24	People feel warm, lethargic, and sleepy. Optimal for unclothed people.
72	22	Most comfortable year-round indoor temperature for sedentary people.
70	21	Optimum for performance of mental work.
64	18	Physically inactive people begin to shiver. Active people are comfortable.

Figure 41-6 Comfortable temperature levels for different activities.

Figure 41-7 The side with the inflated balloon weighs more because of the weight of the air in the balloon.

it because we are continually surrounded by air and air pressure. A simple demonstration can show that air has weight. Place two identical balloons on a balance-beam scale. The scale should show that they are equal in weight. Now inflate one balloon, knot the end, and place it back on the scale. The scale will tilt down on the side with the inflated balloon because of the extra weight of the air (Figure 41-7).

At standard conditions of 70°F and atmospheric pressure 29.92 in Hg, dry air weighs 0.075 lb/ft³. This is its density. Another way to state this is to say that 1 lb of air at standard conditions occupies 13.33 ft³. This is its specific volume. However, the weight and volume of air vary with temperature, pressure, and humidity. In general, they affect weight and volume oppositely: something that increases the volume of the air will decrease its weight. Warmer air weighs less than cooler air. Air volume increases as its temperature increases, causing it to weigh less compared to standard air. This is the principle that hot-air balloons use. The hot air inside the balloon is lighter than the surrounding air, so it rises (Figure 41-8).

The weight of air increases as the air pressure increases. Higher pressures stuff more air molecules into the same space, making it weigh more. Standard atmospheric pressure at sea level is 29.92 in Hg. In general, air pressure decreases as altitude increases. Higher elevations have less air above them pushing down and so have lower atmospheric pressures. This is similar to the effect swimmers feel when diving in water. The increased weight of the water above them causes increased pressure (Figure 41-9). The air in Denver, Colorado weighs less than the air in Atlantic City, New Jersey. This affects the density of the

Figure 41-8 Hot-air balloons rise because the heated air in the balloon is less dense than the surrounding air.

air circulated by fans and the amount of horsepower required to move the same volume of air. A fan in Denver does not require as much horsepower to move the same volume of air as an identical fan in Atlantic City because of the difference in the density of the air (Figure 41-10). The amount of oxygen available for combustion in furnaces is also affected. Furnaces are derated at high altitudes because there is less oxygen available in every cubic foot of combustion air (Figure 41-11).

Humid air is lighter than dry air. One pound of moist air occupies a greater space than 1 lb of dry air. This is because water vapor is less dense than air. This can be seen when boiling water. The steam coming off the boiling water rises because water vapor is not as dense as the surrounding air.

Figure 41-9 Air pressure is affected by elevation; it is higher at lower elevations because of the weight of the air above you; similarly, water pressure increases the further down in the water you go because of the weight of the water above you.

Altitude	Percent of Sea-Level Horsepower
Sea level	1
2,000 ft	0.96
3,000 ft	0.93
4,000 ft	0.89
5,000 ft	0.86
6,000 ft	0.82

Figure 41-10 Fan horsepower vs. altitude.

Altitude	Firing Rate	Percent of Full Capacity
Sea level	100,000 BTU/hr	100%
2,000 ft	96,000 BTU/hr	96%
3,000 ft	94,000 BTU/hr	94%
4,000 ft	92,000 BTU/hr	92%
5,000 ft	90,000 BTU/hr	90%
6,000 ft	88,000 BTU/hr	88%

Figure 41-11 Furnace firing rates are derated based on altitude because both the air and the gas fuel are less dense at higher altitudes.

As the water molecule is absorbed into the air, it is much like putting Styrofoam beads in with sand. Because the Styrofoam beads are much lighter, a box of Styrofoam and sand would become lighter as the proportion of Styrofoam mixed with the sand increases.

SERVICE TIP

Under standard conditions, 1 lb of air occupies approximately 13.33 ft³. That is a space about the size of a box that measures 28.5 in in all dimensions. The weight of the air in a classroom can be estimated by multiplying the length, width, and height of the classroom to determine the classroom’s volume and then dividing that volume by 13.33. For example, a classroom that is 30 ft wide and 40 ft long with a 10 ft ceiling would have 12,000 ft³ of air; and that air would weigh approximately 900 lb (12,000/13.33).

41.4 WATER VAPOR IN THE AIR

All air contains some water (humidity). The amount of water the air can hold is directly related to the temperature: the higher the temperature, the greater the amount of water that air can hold. The amount of water in the air is measured by both specific and relative humidity. Specific humidity is the actual weight of the water in each pound of dry air. Specific humidity is measured in grains per pound of dry air. A grain is a very small unit of weight; there are 7,000 grains in 1 lb.

Relative humidity compares the amount of water in the air to the amount of water the air can hold at a given temperature. For example, the most water the air can hold at 75°F is 130 grains. A sample of air at 75°F with 65 grains of water is at 50 percent relative humidity because it is holding 50 percent as much water as it can hold at that temperature.

41.5 DRY-BULB AND WET-BULB TEMPERATURES

The air dry-bulb temperature is the temperature measured on an ordinary thermometer. Instruments used to measure wet-bulb temperatures are called psychrometers. The wet-bulb temperature is measured by placing a wick soaked with water around the thermometer bulb and moving it rapidly through the air. Water evaporates from the wick, cooling the bulb and lowering the temperature.

The most common psychrometers are called sling psychrometers because they are swung in circles to help evaporate the water from the wet bulb, Figure 41-12a. There are also a number of electronic psychrometers available, such as the one shown in Figure 41-12b). These instruments do not actually evaporate water but measure the relative humidity using electronic sensors. They typically can display relative humidity, dry-bulb temperature, wet-bulb temperature, and dew-point temperature.

The relation of the wet-bulb temperature to the dry-bulb temperature is a measure of the relative humidity. At 100 percent relative humidity, both the wet-bulb and dry-bulb temperatures will be the same because water will not evaporate from the wet bulb. However, at lower relative humidity levels, the wet-bulb temperature will be considerably lower than the dry-bulb temperature. The relative humidity

Figure 41-12 (a) Sling psychrometer for measuring dry-bulb and wet-bulb temperatures to determine relative humidity; (b) electronic psychrometer.

value can be obtained by using either a wet-bulb depression chart or a slide rule provided with the psychrometer. For example, air with a dry-bulb temperature of 80°F and a wet-bulb temperature of 67°F would be at 50 percent relative humidity (Figure 41-13).

Figure 41-13 With the arrow pointing to the dry-bulb temperature of 80°F, read under the 67°F wet-bulb temperature to find the relative humidity of 50 percent.

41.6 DEW-POINT TEMPERATURE

Dew point is another key air characteristic that is affected by the amount of water vapor in the air. The dew-point temperature is the temperature at which the water vapor can condense out of the air. In an air-conditioning system, dehumidification takes place when the air passes over a coil whose temperature is below the dew-point temperature of the air.

As shown in Figure 41-14, when air with a 55°F dew-point temperature passes over the 40°F evaporator coil, the water vapor in the air will condense on the coil and drip into the drain pan.

TECH TIP

As the air velocity through an air-conditioning coil increases, the amount of dehumidification decreases. Conversely, as the velocity of the air slows through a coil, greater dehumidification will occur. You can use slight changes in fan speed to help control an area's humidity. This can be very important along the coast or in areas of particularly high relative humidity.

Figure 41-14 Water condenses on the evaporator coil when the coil temperature is below the dew point of the return air.

Figure 41-15 The lines on the psychrometric chart represent different air properties.

41.7 PSYCHROMETRIC CHART

The psychrometric chart is a graphical representation of air properties (Figure 41-15). Psychrometric charts are used by engineers to plot system performance when designing air conditioning systems. A system plot provides a visual picture of the changes taking place in the air passing through the air conditioner.

The psychrometric chart can show the following air properties:

- **Dry-bulb temperature** Measures the normal air temperature in degrees Fahrenheit and shown with vertical lines (Figure 41-16). The dry-bulb temperatures are shown across the bottom of the psychrometric chart.
- **Wet-bulb temperature** Measures the wet-bulb temperature in degrees Fahrenheit and shown with diagonal lines (Figure 41-17). The wet bulb temperatures are shown along the curved portion on the left-hand side of the psychrometric chart.
- **Enthalpy.** Measures the total heat content of the air in BTU per pound of air. The enthalpy lines are diagonal lines that are nearly parallel to the wet-bulb temperature lines (Figure 41-18). The enthalpy values are shown on the left along a straight line that is roughly parallel to the curved line. Instead of having a separate set of diagonal lines, some charts have the

Figure 41-16 Dry-bulb temperature lines on psychrometric chart.

Figure 41-17 Wet-bulb temperature lines on psychrometric chart.

Figure 41-18 Enthalpy (total heat content) lines on psychrometric chart.

enthalpy values on both the left and right side of the chart. A straightedge is used between them to indicate the enthalpy line (see Figure 41-1).

- **Dew-point temperature** Measures the temperature where water will start to condense out of the air. It is measured in degrees Fahrenheit and is shown with horizontal lines (Figure 41-19). The dew point temperatures are shown along the curved portion on the left-hand side of the psychrometric chart. They are the same numbers used for reading wet-bulb temperature. However, the dew point lines are horizontal while the wet-bulb lines are diagonal.
- **Specific humidity** Measures the weight of water vapor in the air in grains and is shown with horizontal

Figure 41-19 Dew-point temperature lines on the psychrometric chart.

Figure 41-20 Grains of moisture line on the psychrometric chart.

Figure 41-21 Relative humidity lines on the psychrometric chart.

lines (Figure 41-20). The specific humidity readings are shown on the right-hand side of the chart.

- **Relative humidity** Expresses the percentage of water vapor in the air compared to the amount of water vapor the air can hold. Relative humidity is

Figure 41-22 Specific volume lines on the psychrometric chart.

shown by the sweeping curved lines (Figure 41-21). The values are written on the lines.

- **Specific volume** Measures the space in cubic feet occupied by each pound of air. The specific volume lines are diagonal lines with a less severe slope (Figure 41-22). The values are written on the lines.

41.8 PLOTTING POINTS ON THE PSYCHROMETRIC CHART

Any two air properties that use separate lines can be used to plot a point on the psychrometric chart. All the other properties can be determined once the intersection is found. For example, the intersection of 80°F db (dry bulb) temperature and 67°F wb (wet bulb) temperature is shown by the red dot in Figure 41-23. Blue arrows from that point

Figure 41-23 Psychrometric chart with 80°F db and 67°F wb temperatures.

Figure 41-24 Green line between A and B shows a sensible heat change; the red arrows show the temperature change from 70°F to 80°F; the blue arrows show the enthalpy change from 27.5 BTU to 30.5 BTU.

show the values of the other properties at that condition. Summarized, they are:

Dry-bulb temperature	80°F (given)
Wet-bulb temperature	67°F (given)
Dew-point temperature	60°F
Relative humidity	50 percent
Enthalpy	31.4 BTU
Specific humidity	75 grains
Specific volume	13.8 ft ³

41.9 SENSIBLE HEAT AND LATENT HEAT PROCESSES

Nearly all processes will involve a change in sensible heat, latent heat, or both. The exception would be a process whose beginning and ending points lie on the same diagonal

enthalpy line. Processes that cause a horizontal shift from the start to the finish represent a sensible heat change because the air temperature is changing (Figure 41-24). Processes that cause a vertical shift from the start to the finish represent a latent heat change because the air temperature is remaining the same while the specific humidity is changing (Figure 41-25).

Many processes may cause both sensible and latent heat changes. It is possible to use the psychrometric chart to determine the amount of sensible heat change and latent heat change for an air-conditioning process. Plot a third point to form a right triangle between the beginning and ending points of the process. The triangle should have one vertical leg and one horizontal leg. Look up the enthalpy of all three points. The sensible change will be the difference in enthalpy from end to end of the horizontal leg. The latent change will be the difference in enthalpy from end to end of the vertical leg (Figure 41-26).

Figure 41-25 Green line between A and B shows a latent heat change; the red arrows show the specific humidity change from 43 grains to 62 grains; the blue arrows show the enthalpy change from 27.5 BTU to 30.5 BTU.

Figure 41-26 B to C shows the sensible change, while A to C shows the latent change.

41.10 PLOTTING COMMON AIR-CONDITIONING PROCESSES

The changes that take place in the properties of the air during an air-conditioning process can be plotted. Examples of plotting common air-conditioning processes are shown next.

Heating

Figure 41-27 shows the addition of sensible heat. The process is shown moving along a horizontal line to the right. The wet-bulb temperature and enthalpy increase and the relative humidity decreases. The dew-point temperature and the water content do not change. This process involves only sensible heat change.

Cooling with a Dry Evaporator Coil

Figure 41-28 shows the reduction of sensible heat. This process represents cooling with a coil whose temperature is above the dew point of the entering air. The process is

Figure 41-27 Plotting the addition of sensible heat by a furnace on the psychrometric chart.

also shown moving along a horizontal line, but in the opposite direction. The wet-bulb temperature and enthalpy decrease and the relative humidity increases. Again, there is no change in dew point or water content. This process involves only sensible heat change.

Humidifying

Figure 41-29 shows the addition of water. This action is represented by a vertical line moving upward as the specific humidity increases. The only property that does not change is the dry-bulb temperature, which is held constant. Heat is added as evidenced by the increase in enthalpy, but the heat is used to evaporate the water. The wet-bulb temperature, dew point, and relative humidity all increase. This process involves only latent heat change.

Simultaneous Heating and Humidifying

Figure 41-30 shows the simultaneous addition of sensible heat and water. The line representing the operation moves upward to the right. The air picks up both heat and water

Figure 41-28 Plotting the temperature of air being cooled without dehumidification on the psychrometric chart.

Figure 41-29 Plotting the addition of moisture to the air produced by a humidifier.

Figure 41-30 Heat and moisture added by a hot-air furnace with a humidifier.

as it moves through the conditioner. The enthalpy, wet-bulb temperature, specific humidity, and dew-point temperature all increase. The relative humidity could increase, remain the same, or decrease, depending on how much water is added. In actual operation, the amount of heat and water added must match the heat and water lost by the structure to maintain the same temperature and humidity in the building. This process involves both sensible and latent heat change.

Cooling and Dehumidification

Figure 41-31 shows the reduction of both sensible heat and water. This is the traditional refrigerated air-conditioning cycle. The line representing the operation moves downward to the left. The cooling coil both cools the air and condenses water as the air passes through it. The enthalpy, wet-bulb temperature, and dew-point temperature all decrease. The

Figure 41-31 Cooling and dehumidification produced by an air conditioner, plotted on the psychrometric chart.

relative humidity increases, since the air is nearly saturated when it leaves the coil. This process involves both sensible and latent heat change.

Evaporative Cooling

Figure 41-32 shows the process of removal of sensible heat accompanied by a simultaneous increase in water. The process uses evaporation of water to cool the air. The process follows the wet-bulb line in the chart. The dry-bulb temperature decreases as the water in the air and the relative humidity increase. This process essentially converts sensible heat to latent heat; enthalpy is constant.

Figure 41-32 Cooling and humidification produced by an evaporative cooler plotted on the psychrometric chart.

GREEN TIP

The importance of airflow for the proper operation of air conditioning systems cannot be overstated. Poor airflow has become one of the most common problems seen in the field. Systems with inadequate airflow operate inefficiently with a reduced capacity, causing increased energy use. Prolonged operation with inadequate airflow will lead to early liquid floodback and early compressor failure.

41.11 AIRFLOW FUNDAMENTALS

The air in an air-conditioning system moves. Rates are used to describe something that is moving. A rate measurement compares a quantity with a time. The output of a fan is measured in cubic feet per minute (CFM), describing the volume of air in cubic feet that the fan moves every minute. The speed of the air is used to determine the amount of airflow. Speed is also stated as a rate. A speed of 50 miles per hour indicates that a car traveling at that speed for an hour will cover a distance of 50 miles. Airspeed, or velocity, is measured in feet per minute (FPM). Feet per minute describes how far the air will travel in a minute. This still does not really measure how much airflow there is, just how fast it is moving. To determine the volume of the air, multiply the velocity of the air times the area of the hole it is leaving. Air traveling at a rate of 100 FPM through a 1 square foot opening will make a column of air with a volume of 100 CFM.

Example: Calculate the airflow if air is leaving a 24×36 -in hole at a velocity of 50 FPM. The area of the hole is calculated by multiplying $24 \text{ in} \times 36 \text{ in} = 864 \text{ in}^2$. Convert square inches to square feet by dividing by 144: $864 \text{ in}^2 / 144 = 6 \text{ ft}^2$. Alternately, you can convert the dimensions to feet before multiplying. For example $24/12 = 2\text{ft}$; $36/12 = 3\text{ft}$; $2\text{ft} \times 3\text{ft} = 6 \text{ ft}^2$. The airflow in CFM is calculated as $50 \text{ FPM} \times 6 \text{ ft}^2 = 300 \text{ CFM}$.

TECH TIP

Ventilation hoods work by moving air at high enough speeds to suck in surrounding air and effectively capture the fumes, smoke, grease, or other small particles in the airflow. They have a specification called the capture velocity, which is how fast the air must move to capture particular contaminants and move them out through the vent system. The capture velocity is measured in feet per minute (FPM).

SERVICE TIP

Standard airflow through air-conditioning evaporator coils has been 400 CFM per ton for many years. Most air-conditioning equipment will operate safely at 400 CFM per ton.

Figure 41-33 Digital rotating vane anemometer.

41.12 USING ANEMOMETERS AND FLOWHOODS TO MEASURE AIRFLOW

Anemometers measure air velocity (Figure 41-33.). They are used to measure the velocity of the air leaving registers and grilles to calculate airflow. Taking accurate measurements is complicated by the fact that air does not travel uniformly through all parts of the register or grille. This can be remedied by taking several readings and averaging them. Some anemometers will take a real-time average, making this fairly easy to do (Figure 41-34.). For calculating CFM, another complicating factor comes in: determining the area of the register. A register that measures 6 in by 10 in does not have a free area of 60 in^2 because some of that space is taken up by the metal bars of the grille. The free area can vary a lot depending on the design of the register or grille. The only reliable method is to look up the free area in the manufacturer's literature.

SERVICE TIP

A small pyramid-shaped cone can be used to direct the air through an unobstructed hole with a known free area. A cone with a free area of 1 ft^2 is ideal since the average velocity would also be the CFM.

Figure 41-34 This anemometer can average the velocity reading over the period of time the reading is taken.

Figure 41-35 Flowhood.

Flowhoods solve the problem of not knowing the free area by directing all the air through an opening with a known area (Figure 41-35). They measure the average velocity and calculate the volume using the average velocity. See Unit 73, Testing and Balancing, for more information on anemometers, flowhoods, and airflow measurement.

41.13 TYPES OF DUCT PRESSURE

Air moves through ductwork for only one reason: it travels from an area of high pressure to an area of low pressure. The blower provides the pressure difference to move the air through the ductwork. The amount of air the blower can move and the amount of energy needed to move the air is controlled by the resistance to airflow from the ductwork and all the system components in the airstream. In general, fans have the highest capacity when they are in open air, without any restriction to airflow. This is called free-air in fan ratings. The capacity of the fan decreases when it must move air against a pressure difference. A pressure difference is created when air is constrained by ductwork. There are two kinds of pressure created by moving air through the duct system: static pressure and velocity pressure (Figure 41-36).

Static Pressure

The word *static* means stationary, or not moving. When you blow up a balloon, the air pushes out evenly in all

Figure 41-36 The two pressures created by air moving through a duct are static pressure and velocity pressure; total pressure is the sum of these two pressures.

Figure 41-37 Static pressure in a duct like the pressure inside a balloon—pushing out in all directions.

directions, creating static pressure. When a fan blows air into a confined space, it creates static pressure on all the surfaces of the confined space. When a fan moves air through ductwork, it pressurizes the duct system in much the same way a balloon is inflated. Static pressure in the duct pushes in all directions (Figure 41-37). If a large box is placed over the outlet of a blower, pressure will build up in the box and will be distributed evenly in all directions. In air conditioning, this box is called the supply plenum.

Velocity Pressure

Velocity pressure is pressure created by moving air. Velocity pressure only pushes in the direction of airflow. If the end of an inflated balloon is released, the balloon will fly around the room because the pressure in the balloon goes from the high static pressure inside the balloon to outside of the balloon where the pressure is lower. As this happens, static pressure is converted to velocity pressure. Velocity pressure is the pressure exerted by moving air. The word *velocity* means speed. The air now has velocity because it is moving, creating velocity pressure. If a hole is cut in the supply plenum, the static pressure will force air out of the hole, creating velocity pressure. The pressure in the supply plenum will drop as some of the static pressure is converted to velocity pressure. Total pressure is the combination of static pressure and velocity pressure. The difference in total pressure from one area to another is what pushes the air forward.

Pressure Changes

Static pressure can be transformed into velocity pressure, as in the example of the balloon. Velocity pressure can also be transformed to static pressure. In the example of the cardboard box over the blower, velocity pressure is transformed into static pressure. As the air moves through the blower it achieves significant velocity. When the moving air hits the box, its velocity, and thus its velocity pressure, drops to nothing. However, the energy does not simply disappear; it is transformed into static pressure, pushing out in all directions.

As a general rule, changes in duct geometry affect static and velocity pressure in opposite ways. An example would be a change in duct diameter. If a duct decreases in size, the velocity of the air moving through it will increase because the same amount of air now must pass through a smaller opening. The only way it can do that is to move

Figure 41-38 Inclined manometer for measuring air pressure. (Courtesy Dwyer Instruments, Inc.)

faster. This increases the velocity pressure in the duct. The energy for the increased velocity pressure comes at the expense of static pressure. Since more energy is being used to move the air forward, less is available for pushing out in all directions.

It should be noted that increasing or decreasing the amount of airflow will cause a proportional change in both the static and velocity pressures. Pushing more air through the same size duct will increase both the static and velocity pressures. Another important exception is that when static pressure is reduced because of friction loss, velocity pressure is not increased. In this case, the static pressure is converted to heat, not velocity pressure.

41.14 READING DUCT PRESSURE

Duct pressures are read in inches of water column with an incline manometer (Figure 41-38), a digital manometer (Figure 41-39), or a magnehelic gauge (Figure 41-40). Three types of pressure readings are taken in duct systems: total pressure, static pressure, and velocity pressure.

Figure 41-39 Electronic digital manometer used for taking accurate duct pressure readings. (Courtesy of Extech Instruments, A FLIR Company)

Figure 41-40 Magnehelic gauge can be used for taking accurate duct pressure readings.

SERVICE TIP

If a manometer reading must be taken in a run of flex duct, cover the area with duct tape before cutting into the flex duct. This will prevent excessive damage to the flex duct.

Measuring Total Pressure

Total pressure is read by placing the manometer sensing tube so that air flows directly into the tube opening, as shown in Figure 41-41. Placing the sensing tube directly into the airstream measures both velocity pressure and static pressure. It senses the velocity pressure because the opening is facing the flow of air; and it senses the static pressure because static pressure pushes out in all directions.

Measuring Static Pressure

The trick to measuring static pressure is to place the probe where it will not pick up any velocity pressure. Placing the probe perpendicular to the airflow is the most common method of reading static pressure (Figure 41-42).

Measuring Velocity Pressure

Velocity pressure cannot be read directly at a single point because static pressure is present anywhere a probe is placed. The velocity pressure is the difference between the total and static pressures and can be read by subtracting the static pressure from the total pressure. Velocity pressure is read by placing one probe in the airstream to

Figure 41-41 Manometer measuring total air pressure, in inches of water column.

Figure 41-42 Manometer measuring static pressure, in inches of water column.

Figure 41-43 Manometer measuring velocity pressure, in inches of water column.

measure total pressure and connecting a probe on the opposite side of the manometer to read static pressure, as shown in Figure 41-43.

The velocity pressure is useful in measuring the velocity of air in a duct. The formula to convert velocity pressure to velocity is

$$4,005\sqrt{\text{velocity pressure}}$$

Some magnehelic gauges and inclined manometers are calibrated to read duct velocity directly in feet per minute. Most digital manometers can automatically convert velocity pressure to velocity. The *pitot tube* (pronounced "pea-toe") is a single probe that can be inserted in the duct and connected to the manometer for reading velocity pressure (Figure 41-44). It does this by measuring both total and static pressures, as shown in Figure 41-45.

SERVICE TIP

Airflow through ductwork can be very uneven. The velocity is higher toward the center of the duct and lower close to the outside of the duct. To get accurate airflow measurements, it is necessary to take several readings at different points in a cross-section of the duct to get an average. This is called traversing the duct. This will be discussed in more detail in Unit 73, Testing and Balancing Air Systems.

Figure 41-44 A pitot tube measuring velocity pressure by measuring both total pressure and static pressure.

Figure 41-45 A pitot tube reading velocity pressure in a duct.

41.15 CALCULATING AIR-CONDITIONING SYSTEM PERFORMANCE

The psychrometric chart can be useful in checking the performance of air-conditioning equipment, as shown in the following example. Because the wet bulb and enthalpy lines nearly overlap, the wet-bulb temperature is really all that is needed to determine the enthalpy. Four measurements are necessary to calculate the actual cooling capacity of an air-conditioning system:

- Wet-bulb temperature of the entering air
- Wet-bulb temperature of the leaving air
- Dry-bulb temperature of the leaving air
- Airflow volume in CFM
- Entering-air dry bulb (only necessary if sensible and latent values are to be calculated)

The wet-bulb temperatures are used to determine the enthalpy of the entering and leaving air. The difference in the enthalpy between the entering and leaving air will show the amount of heat lost from each pound of air. The dry-bulb and wet-bulb temperatures of the leaving air are used to determine the volume of each pound of air. The CFM and this volume are used to determine the pounds of air per minute. The total cooling capacity in BTU per minute is

Figure 41-46 The enthalpy of the entering air is 33 BTU/lb, and the enthalpy of the leaving air is 28 BTU/lb.

determined by multiplying the enthalpy difference in BTU times the pounds per minute of air. This value is multiplied by 60 to show the cooling capacity in BTU/hr. This can be summarized by the following formula:

Enthalpy change = enthalpy of air in – enthalpy of air out

Pounds/minute of air = CFM airflow/cubic feet per pound of air

BTU/hr = 60 × pounds of air/minute × BTU/lb enthalpy change

the enthalpy of the supply air is 28 BTU/lb and the volume of the supply air is a little less than 13.5 ft³/lb. To calculate the system capacity:

$$\text{Enthalpy difference} = 33 \text{ BTU/lb} - 28 \text{ BTU/lb} = 5 \text{ BTU/lb}$$

$$\text{Pounds/minute circulated} = 850 \text{ ft}^3/\text{min} / 13.5 \text{ ft}^3/\text{lb} = 63 \text{ lb/min}$$

$$\text{Total capacity calculation} = 60 \times 63 \text{ lb/min} \times 5 \text{ BTU/lb} = 18,900 \text{ BTU/hr}$$

Example Calculation

An air conditioner is operating with a return air temperature of 80°F db, 69°F wb. The supply air temperature is 63°F db and a 61°F wb with an airflow of 850 CFM. Referring to Figure 41-46, the enthalpy of the return air is 33 BTU/lb,

Sensible and Latent Capacity Calculations

To determine the sensible and latent capacities of this system, a third point is added to form a right triangle (Figure 41-47).

Figure 41-47 The enthalpy of the third point that forms the right triangle is 31 BTU/lb.

Figure 41-48 Mixed-air example.

This point is at 80°F db and 66°F wb. The enthalpy of this point is 31 BTU/lb. To calculate sensible and latent capacities:

$$\text{Sensible change} = 31 \text{ BTU/lb} - 28 \text{ BTU/lb} = 3 \text{ BTU/lb}$$

$$\begin{aligned} \text{Sensible capacity} &= 60 \times 63 \text{ lb/min} \times 3 \text{ BTU/lb} \\ &= 11,340 \text{ BTU/hr} \end{aligned}$$

$$\text{Latent change} = 33 \text{ BTU/lb} - 31 \text{ BTU/lb} = 2 \text{ BTU/lb}$$

$$\begin{aligned} \text{Latent capacity} &= 60 \times 63 \text{ lb/min} \times 3 \text{ BTU/lb} \\ &= 7,560 \text{ BTU/hr} \end{aligned}$$

41.16 AIR MIXTURES

It is sometimes necessary to calculate the expected result of mixing two different airstreams. Ventilation air in commercial systems is one example. Most codes require at least 25 percent fresh ventilation air in commercial installations. This means that 25 percent of the air entering the conditioned space came from outside. Typically, the air from outside is called makeup air, the air returning from the building is called return air, and the result of mixing the two airstreams is called mixed air (Figure 41-48). The expected temperature of the mixed air can be determined by the following formula:

$$\begin{aligned} \text{Mixed-air temperature} &= (\text{makeup-air temperature} \times \text{percent outside air}) \\ &+ (\text{return-air temperature} \times \text{percent return air}) \end{aligned}$$

For example, a system with 25 percent fresh air with an outdoor temperature of 50°F and a return-air temperature of 70°F would be calculated as follows.

$$\begin{aligned} \text{Mixed-air temperature} &= (50^\circ\text{F} \times 0.25) + (70^\circ\text{F} \times 0.75) \\ &= 12.5^\circ\text{F} + 52.5^\circ\text{F} \\ &= 65^\circ\text{F} \end{aligned}$$

Similar calculations can describe the final specific humidity of the mixed air if the water vapor content is also required. By determining both the temperature and specific humidity of the mixed air, all aspects the mixed air can be determined. The formula to determine the mixed-air specific humidity is:

$$\begin{aligned} \text{Mixed-air grains} &= (\text{outdoor-air grains} \times \text{percent outdoor air}) \\ &+ (\text{return-air grains} \times \text{percent return air}) \end{aligned}$$

In the previous example, if the outdoor-air specific humidity is 40 grains and the return-air specific humidity is 28 grains:

$$\begin{aligned} \text{Mixed-air grains} &= (40 \text{ grains} \times 0.25) + (28 \text{ grains} \times 0.75) \\ &= 10 \text{ grains} + 21 \text{ grains} \\ &= 31 \text{ grains} \end{aligned}$$

The mixed air will have a temperature of 65°F and a specific humidity of 21 grains. All other properties can be determined using the psychrometric chart.

UNIT 41—SUMMARY

The study of air and its properties is called psychrometrics. The properties of air include weight, volume, temperature, water content, and heat content. Temperature and humidity are both important for human comfort. The body regulates its internal temperature by dissipating heat to its surroundings through conduction, convection, radiation, and evaporation. The weight and volume of air is affected by its temperature. Increasing the temperature of air increases its volume and decreases its weight. Decreasing its temperature decreases its volume and increases its weight. The amount of water in the air is measured by comparing a regular dry-bulb temperature to a wet-bulb temperature. The closer the two temperatures are to each other, the higher the relative humidity. Specific humidity is the amount of water in the air measured in grains. Dew point is the temperature that water vapor can start to condense out of the air.

The psychrometric chart is a graphical representation of air properties. If two properties are known, the other properties can be determined from the chart. Processes that cause a horizontal shift from the start to the finish represent a sensible heat change because the air temperature is changing. Processes that cause a vertical shift from the start to the finish represent a latent heat change because the air temperature is remaining the same while the specific humidity is changing. The psychrometric chart can be used to calculate the actual cooling capacity of an air-conditioning system by measuring the entering-air wet bulb, the leaving-air wet bulb, and the airflow.

Air velocity is measured in feet per minute (FPM). Anemometers are used to measure air velocity. Air volume is measured in cubic feet per minute (CFM). CFM can be calculated by multiplying air velocity in FPM times the free area of the register or grille the air is moving through. Free area is the actual open area in a grille after subtracting the space taken up by the louvers and bars. Air volume can be measured directly using a flowhood. Fans move the air through the forced-air duct system by creating a pressure difference. Air moving through ductwork creates both static pressure and velocity pressure. Static pressure pushes outward in all directions, like the pressure inside a balloon. Velocity pressure pushes air forward in the direction of airflow. Total pressure is the combination of static and velocity pressure. The pressure in a duct system is measured in inches of water column using an inclined manometer, an electronic manometer, or a magnehelic gauge.

WORK ORDERS

Service Ticket 4101

Customer Complaint: House Feels Stuffy

Equipment Type: High-Efficiency Split-System Air Conditioner 2-Ton Condensing Unit with AHRI Matched 2½-Ton Evaporator Coil

A customer complains that his house feels stuffy since his new high-efficiency system was installed even though the thermostat is at the same setting that he used to keep the old system. The technician notices that there does not seem to be any water coming out of the evaporator drain line. Measurements of the return and supply air show 80°F db, 68°F wb return air, and 64°F db, 63°F wb supply air. Consulting the psychrometric chart, the technician sees that the specific humidity is the same for both readings, indicating that all the cooling is sensible cooling and no water is being removed. The indoor fan ECM speed control board is set to 3 tons at 450 CFM per ton, but the cooling capacity of the condensing unit is only 2 tons. The technician moves the fan speed tap to 2 tons at 350 CFM per ton, reducing the overall airflow from 1,350 CFM to 700 CFM. New readings are taken after operating for 15 minutes at the new fan speed. The return air is about the same, but the supply air temperature has changed to 62°F db and 58°F wb. Water starts coming out of the evaporator drain.

Service Ticket 4102

Customer Complaint: Drafty Air Coming from Supply Registers in Winter

Building: Commercial Office Building with Fresh-Air Ventilation System

The customer complains that the air coming out of the supply registers feels drafty and the building is chilly. Upon arrival, the technician notices that the building has an unusually high positive pressure; the doors are almost standing open. The technician measures the air leaving the supply air registers and finds it is 85°F. Next, the boiler and water pumps are checked. The water flow is correct and the boiler appears to be operating correctly. The temperature rise across the hot water coil is 50°F, but the air going into the coil is only 40°F. The technician measures the outdoor air temperature as 32°F and the return-air temperature as 64°F. A quick calculation confirms that the air mixture is 75 percent outside air. For 25 percent outdoor air, the mixed-air temperature should be 56°F. An adjustment of the minimum air position of the damper control fixes the problem, and the supply registers start delivering 100°F supply air. After the building heats up, the supply air rises to 110°F.

Service Ticket 4103

Customer Complaint: Indoor Swimming Pool Area Is Muggy

Building: Large Residence with Indoor Pool Area that Is Not Air-Conditioned but Is Ventilated

The customer complains that the pool area feels oppressively muggy and that water is running down the walls. The technician takes both a dry-bulb and a wet-bulb temperature and finds that the wet bulb is only 2°F cooler than the dry bulb. The technician suspects that there may be a problem with the ventilation air and checks the ventilation air inlet. There is very little ventilation airflow. The technician finds that the inlet screen to the ventilation blower is clogged with leaves. Once the leaves are cleared, the ventilation air returns. After an hour of proper ventilation, the wet-bulb temperature and relative humidity in the room drop to normal levels.

Service Ticket 4104

Customer Complaint: Finished Basement Is Musty Smelling

Building: Residence with a 1,000-ft² Finished Basement

The customer complains that the basement is musty smelling. The temperature is fine, but the basement smells musty and feels dank. The technician takes both a dry-bulb and a wet-bulb reading in the basement. The dry bulb is 70°F and the wet bulb is 65°F. The technician aligns the dry bulb and wet bulb on the scales built into the sling psychrometer and reads a relative humidity of 76 percent. Next, the technician consults a psychrometric chart and finds that the difference in the specific humidity of 76 percent relative humidity and 50 percent relative humidity is about 30 grains. The technician calculates the basement volume at 8,000 ft³ (1,000 ft² × 8 ft), and the weight of air at 588 lb (8,000 ft³/13.6 ft³/lb). The house construction is average, consistent with one air change per hour. The technician recommends a dehumidifier with a capacity to remove the water in one air change. The amount of water needing to be removed is 588 lb of air × 30 grains/lb = 17,648 grains = 2.5 lb of water, about 2.5 pints. He recommends a unit with a capacity of 2.5 pints of water per hour, or 60 pints per day.

Service Ticket 4105

Job: Measure Airflow Through New Supply Register

Building: Residence with a Finished Basement

A technician is sent to check the installation of a newly installed register in a finished basement. The plans call for an airflow of 150 CFM through the 8 × 10 register. The technician looks up the register free area and finds that it is 48 in². He uses an averaging anemometer to take the average velocity of the air leaving the register. The average velocity measures 450 FPM. He converts 48 in²

to square feet: $48/144 = 0.33 \text{ ft}^2$. Finally, the free area in square feet is multiplied by the velocity of 450 FPM to arrive at a CFM of 150 CFM.

Service Ticket 4106

Job: Measure Airflow in a Duct

Equipment Type: Residential Split System

A service technician is sent to check the airflow in the trunk duct of a new residential split-system installation to ensure that the air velocity is less than 1,000 FPM. She makes a small 1/4-in hole in the duct and inserts a pitot tube. Next, she connects the total pressure hose to the high input of the magnehelic gauge and the static pressure hose to the low input on the magnehelic gauge. The magnehelic reads a velocity pressure of 0.06 in water column (wc). The technician calculates the velocity: $4,005 \times \sqrt{0.06} = 981 \text{ FPM}$.

UNIT 41—REVIEW QUESTIONS

- What three environmental conditions have the most effect on comfort?
- List four ways the human body expels heat.
- Why does the air's relative humidity affect comfort?
- How is the air volume affected by temperature?
- What is the relationship between air volume and air weight (density)?
- What are grains, and what air property is measured in grains?
- In general, which is heavier: humid air or dry air?
- What is a wet-bulb temperature reading?
- How is relative humidity measured?
- What is the dew-point temperature?
- What is the difference between specific humidity and relative humidity?
- What is a psychrometric chart?
- List the air properties that are plotted on a psychrometric chart, and give a brief description of each.
- What would the mixed-air temperature be for a system with 20 percent outdoor air if the outdoor temperature is 10°F and the return-air temperature is 75°F?
- Identify the scales represented by the lines on Figure 41-49.

16. Use the psychrometric chart in Figure 41-1 to look up the missing data in this table.

Dry Bulb	Wet Bulb	Relative Humidity	Dew Point	Specific Humidity	Volume	Enthalpy
72				59 grains		
	61	45%				
85		60%				
			45			28
85	70					

- What pressure units are used for measuring duct pressures?
- What two pressures are created by air moving through the duct system?
- What instruments are used for measuring duct pressure?
- Explain how to take a static pressure reading on a duct system.
- Explain how to take a velocity pressure reading on a duct system.
- What units are used to measure air velocity?
- What tools are used to measure air velocity?
- What units are used to measure air volume?
- What is the airflow through a register with a free area of 72 in² if the air velocity is 300 FPM?
- How does a flowhood measure airflow?
- What is the velocity of the air in a duct with a total pressure of 0.15 in wc and a static pressure of 0.1 in wc?
- What is the airflow in CFM through a 10 × 20-in duct with a total pressure of 0.15 in wc and a static pressure of 0.1 in wc?
- What is the typical airflow per ton of residential air-conditioning equipment?

UNIT 42

Air Filters

OBJECTIVES

After completing this unit, you will be able to:

1. list the types of air filters.
2. list the types of air contaminants.
3. explain the MERV efficiency rating system.
4. explain how an electronic air cleaner works.
5. discuss the importance of pressure drop and airflow rating when selecting an air filter.

42.1 INTRODUCTION

Total comfort involves more than heating and cooling the air. As the public becomes more aware of indoor air quality and energy efficiency, they also are becoming more aware of air cleanliness. Advanced air cleaners that remove minute particles from the air are gaining in popularity as customers expect their systems to be part of an indoor environmental conditioning system. Installing and servicing advanced filters is part of an air-conditioning technician's job description.

42.2 AIR CONTAMINANTS

Anything in the air besides nitrogen, oxygen, and the normal mix of trace gases can be considered a contaminant. Common air contaminants include dust, smoke, biological contaminants, and chemical contaminants. The size of contaminant particles in the air is measured in microns. A micron is an SI unit of measurement equal to 1/1,000 of a millimeter. There are approximately 25,400 microns in an inch. A human hair is about 100 microns in thickness. The particles suspended in the air vary in size from under 0.3 microns to greater than 10 microns (Figure 42-1). Particles

must be 10 microns or larger to be visible with the naked eye. Over 99 percent of the particles in the air are below 1 micron in size.

The chart in Figure 42-1 shows that pollen is relatively easy to remove, but a filter must be capable of removing particles down to 0.3 microns in size to remove airborne bacteria. The smallest particles of tobacco smoke are as small as 0.01 microns. These minute particles can be removed from the air with either a very-high-efficiency mechanical filter or an electronic air cleaner. The common throwaway filters used in many furnaces are only capable of removing particles over about 10 microns in size. They are fine for pollen and sawdust but not very effective on tobacco smoke.

42.3 TYPES OF AIR FILTERS

The most common types of air filters use mechanical media to trap contaminants. Figure 42-2 shows a magnified view of fine fiber filter media. Some filters use electrostatically charged media or a viscous coating to help attract particles in the air. Filters that use an electrostatic charge can be

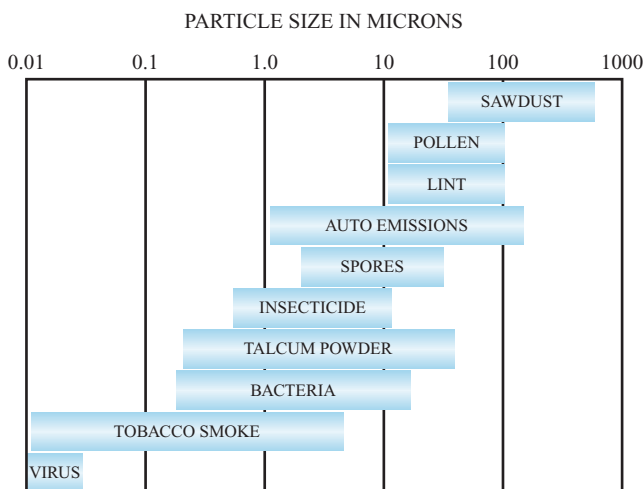

Figure 42-1 Size of common air contaminants.

Figure 42-2 Magnified view of a fine fiber media used for filtration. (Courtesy of NIOSH)

Figure 42-3 Air filters are available in a wide variety of efficiencies and configurations. (Courtesy of AAF International)

divided into mechanical media filters with an electrostatic charge and electronic air cleaners that use an active power supply and charged metal plates. Mechanical filters are available in a wide variety of constructions and efficiencies from simple panel filters to extended surface filters like pleated filters, cube filters, and bag filters (Figure 42-3). They can be generally classified by their efficiency as low-efficiency, medium-efficiency, or high-efficiency particle air filters (HEPA).

Low-Efficiency Panel Filters

Most residential equipment comes with a low-efficiency, 1-in-thick panel filter installed (Figure 42-4). Commercial equipment typically uses similarly constructed 2-in filters. The purpose of these filters is to protect the equipment; they do little for cleaning the air. They are inexpensive and create very little pressure drop across the filter.

Pleated Medium-Efficiency Filters

Pleated 4-in and 5-in medium-efficiency filters are available for both residential and commercial installation (Figure 42-5). These filters do improve the air quality of the building, as well as protect the system. Medium-efficiency filters create a higher pressure drop across the filter, but the pressure drop is still usually within the operating limits of most residential and light commercial equipment.

HEPA Filters

HEPA stands for high-efficiency particulate air filter. HEPA filters were originally developed to remove radioactive contaminants from the air during the development of the atomic bomb. HEPA filters have a very large extended surface area of submicron media (Figure 42-6). Their surface area is extended by forming long bags or large pleats with deep folds. HEPA filters have a very high efficiency at removing very small particles. There are many different standards for HEPA filters, ranging from 99.97 percent efficiency with particles down to 0.3 microns to 99.99 percent efficiency with particles down to 0.12 microns. HEPA filters typically create too high a pressure drop to be used in residential applications. They are used in commercial applications like clean rooms and surgical suites, where removing airborne contaminants is essential.

Figure 42-4 Most residential air-conditioning equipment is supplied with low-efficiency 1-in panel filters.

Figure 42-5 Medium-efficiency pleated filter.

Figure 42-6 HEPA filter. (Courtesy of Camfil Farr)

SERVICE TIP

In some commercial applications, a prefilter is used in front of HEPA filters to extend the life of the more expensive HEPA filters. In some applications, this prefilter media can be mounted on spools so that new filter material can be simply unwound from one spool as the dirty filter material is wound on the takeup spool. The dirty spool of filter material is significantly heavier than a clean spool.

42.4 AIR FILTER RATINGS

There are four important factors to be considered when choosing an air filter: the size of the contaminants the filter must remove, its efficiency at removing the contaminants, the airflow the filter is rated to handle, and its resistance at the rated airflow.

Filter Efficiency

Many different methods have been devised to measure air filter efficiency. The two most commonly used methods are called the filter arrestance and the dust spot efficiency. The arrestance method measures the weight of the material captured by the filter and compares it to the weight of the test material that was released. A filter with an efficiency 50 percent arrestance captures half of the material passing through the filter when measured by weight. Special test dust with calibrated particle sizes is used for these tests. Although many filters are advertised by stating an average arrestance percentage, filter efficiency is not as simple as a single percentage.

All filters capture different size particles at different levels of efficiency. A filter that removes 99 percent of the particles larger than 10 microns may only remove 1 percent of the particles smaller than 1 micron. But since large particles weigh more than small particles, the average arrestance efficiency can be quite high even though most of the particles pass through.

The dust spot efficiency test is designed to measure a filter's ability to remove very small particles that can easily pass through many filters and cause staining on walls and surfaces. The dust spot method uses atmospheric dust instead of calibrated test dust. Air is passed over test paper to achieve a stain from deposits of small particles in the air. This is done both before and after the filter. The efficiency is calculated by comparing the amount of "clean" downstream air required to create the same stain as the dirty upstream air.

Filter efficiency ratings are complicated by the fact that the efficiency of all filters changes as they become dirty. Most mechanical filters become more efficient as they fill with particles and the space for particles to pass through becomes smaller. For this reason, many manufacturers advertise a peak arrestance efficiency that is measured when the filter is ready to be changed.

ASHRAE Standard 52.2-2007 addresses these problems by establishing a rating system that measures the arrestance of particles in twelve different ranges of size (Figure 42-7). The minimum efficiency reporting value, or MERV, looks at the efficiency of a filter over each range with different levels of filter loading. "Filter loading" is a term that describes the amount of material the filter has collected. The minimum efficiency for each range is then used to determine the filter's MERV rating. MERV ratings range from 1 for the lowest efficiency filters to 20 for the highest efficiency filters. Figure 42-7 shows the specifications for the MERV ratings. As a filter's MERV rating increases, so does its pressure drop.

One advantage of the MERV rating is that a user can match the MERV rating to the size of contaminant that must be removed. Filters with a relatively low MERV rating can effectively remove pollen, but a high MERV rating is required to remove bacteria.

Airflow

Filters have a maximum airflow rating. Exceeding the airflow rating of a filter will decrease its efficiency and increase the pressure drop across the filter. Operating a filter at decreased airflow levels will increase its efficiency and decrease its pressure drop. The recommended airflow is based on the filter face velocity—that is, the speed of the air passing through the filter. Increased airflow produces increased airspeed, which reduces the effectiveness of the filter.

TECH TIP

It is important to understand that a MERV rating should always be accompanied by a specified air velocity. Air velocities greater than the velocity tested will result in decreased filter performance.

Pressure Drop

Pressure drop is created across an air filter because of its resistance to airflow. This resistance ranges from 0.1 in wc for clean low-efficiency filters to over 1 in wc for some HEPA filters. Filter manufacturers specify the recommended final

Composite Average Particle Efficiency					
MERV	Range E1 0.3 – 1.0 microns	Range E2 1.0 – 3.0 microns	Range E3 3.0 – 10.0 microns	Effective On	Applications

20	>99.9999% of 0.10 – 0.20 micron particles				

Figure 42-7 MERV parameters.

pressure drop for their filters. This is the maximum pressure the filter is designed to withstand. Typically, the final pressure is produced when the filter is holding its maximum capacity of dirt. The filter must be changed at this point. However, most filters should be changed before they reach this point. Most residential air-conditioning equipment cannot operate correctly at pressure drops exceeding 0.5 in wc across the blower. All of that cannot be used for the filter—some of that pressure drop is used by coils, ductwork, and registers. Most of these systems will not move enough air if the pressure drop across the air filter starts to exceed 0.2 in wc. An air filter in a residential air-conditioning system with a pressure drop of 0.5 in wc across it is letting very little air through.

The filter's airflow resistance can be measured with an inclined manometer, digital manometer, or magnehelic gauge. It is common practice on large commercial central systems to include a magnehelic gauge or inclined manometer to check the differential pressure across for the filter section (Figure 42-8). This instrument compares the air pressure on the upstream and downstream sides of the filter assembly. The gauge on the instrument indicates when the filters should be changed.

SERVICE TIP

There are 1-in pleated high-efficiency filters for sale whose pressure drop when clean approaches the limit of most residential equipment. These filters cause airflow problems for many systems when they become just a little dirty. Always check a filter's airflow rating and pressure drop, not just its advertised efficiency. There are many filters for sale that simply will not work in most residential systems.

42.5 MECHANICAL FILTRATION

Mechanical air filters work by passing the air and contaminants through a media. The contaminants get stuck in the fibers and the air passes through. A number of materials have been used as the filtering media, including coarse glass fibers, animal hair, vegetable fibers, synthetic fibers, metallic wool, expanded metals and foils, crimped screens, random matted wire, and synthetic open cell foams (Figure 42-9). In

Figure 42-8 Inclined manometer reading pressure drop across air filter.

general, finer fibers produce higher filter efficiency. Filter efficiency also increases as the fiber density increases. However, the air pressure drop across the filter also increases as the filter density increases. The efficiency of mechanical filters increases as the filter becomes dirty because it becomes more and more difficult for particles to pass through the filter. The pressure drop across the filter also increases as the filter gets dirty, reducing the airflow through the filter.

Filter Coatings

The efficiency of coarse fiber media is sometimes increased by coating the media with a viscous substance, such as oil, which acts as an adhesive to the airborne particles coming into contact with it. Another technique is to use materials with an electrostatic charge to attract particles. One problem with these strategies is that they lose their effectiveness as the filter becomes dirty.

Extended-Surface-Area Filters

The area of the filter material exposed to the air can be extended to improve efficiency and minimize the pressure drop created by denser filter material. Extended-area filters are made of random fiber mats or blankets of bonded glass fiber, wool felt, or synthetic materials. Pleating of the media provides a larger filter surface area compared to the face

Figure 42-9 Different filter media; from top left; expanded metal, polyester, foam, hog's hair, light density fiberglass, pleated high density fiberglass.

area. This allows for higher filtering efficiency at a reasonable pressure drop. The efficiency of uncoated extended-surface-area filters is usually higher than the viscous coated coarse fiber filters. In addition to their effectiveness, the extended surface filters have a larger dust-holding capacity for longer periods of use.

42.6 PANEL FILTERS

The low-efficiency filters that come as standard equipment on forced-air heating and cooling equipment are panel filters. Both disposable and washable panel filters are available. The dust-holding capacity of panel filters is generally low because of the limited amount of media in them. They need frequent replacement or cleaning; typically every month. These filters protect the equipment but do not do much for cleaning the air.

SERVICE TIP

Panel filters are directional; the airflow is intended to flow through the filter in only one direction. The direction is clearly marked on the side of the filter with an arrow (Figure 42-10). Look for the directional arrow when installing panel filters and install the arrow pointing toward the unit.

Disposable Panel Filters

Disposable panel filters consist of a cardboard frame with a grill to hold the filter material in place (Figure 42-11). The filter media is made of glass fibers that are loosely woven on the entering-air side and more densely packed on the leaving air side. Some makes also have the fiber media coated with an adhesive substance to attract and hold dust and dirt. Filter thickness is usually 1 in for residential equipment and 2 in for commercial equipment. These filters typically have an initial clean resistance of 0.1 in wc with a face velocity of 300 FPM. The maximum face velocity is typically around 300 FPM, and the maximum final pressure drop is typically between 0.3 to 0.5 in wc.

Figure 42-10 The directional arrow on panel filters should point toward the unit.

Figure 42-11 Throwaway filter.

Figure 42-12 Reusable filter.

Washable Panel Filters

Permanent washable panel filters are also available. These filters may be removed, cleaned with detergent, dried, and reinstalled. They typically have a metal or plastic frame with a cleanable media (Figure 42-12). The media is typically expanded metal or foam. Another washable filter is the hog's hair filter (Figure 42-13). It is made from hog's hair, bonded together in a mat. These filters have enough rigidity that they do not need a frame, but they do frequently have metal rods running through them to help stiffen them.

SERVICE TIP

Getting the homeowner to keep filters clean is not easy, and dirty filters are probably the main contributor to malfunctioning equipment. As the mechanical filter clogs with dirt, airflow is reduced to a point where the cooling coil will freeze, causing compressor failure. In a heating system, dirty filters can cause overheating and reduce the life of the heat exchanger or cause nuisance tripping of the limit switch. Operating costs increase with loss of efficiency.

Figure 42-13 Hog's hair filter.

Figure 42-14 Pleated replaceable media filter.

42.7 RENEWABLE-MEDIA FILTERS

Renewable-media filters keep the structural components of the filter and replace the media when it becomes dirty. Two common types of renewable-media filters are pleated filters and moving-curtain filters. Renewable-media pleated filters use a frame and combs to support and separate the pleated material (Figure 42-14). When the material becomes dirty, the media is replaced, but the existing frame and combs are reused for the replacement media. Similar filters are available that hold the pleated filter material in a cardboard frame. For these, the entire cardboard box is replaced (Figure 42-15).

Renewable pleated filters are used in residential and light commercial applications. These filters are generally medium efficiency. The increased amount of media gives these filters a much higher dust-holding ability. They do not require changing as often as the disposable panel filters. Most pleated 4-in and 5-in-deep extended-media filters will last between 6 months to a year between changes.

The moving curtain filter is an automatic moving curtain with the random fiber medium, treated with a viscous material and furnished in roll form. The material rolls down

Figure 42-15 Pleated boxed filter.

from the top of the unit. As the exposed area becomes saturated with dirt, a clean section is automatically rolled into place. The used portion is collected in a roll at the bottom and thrown away. A fresh roll is again placed at the top to the unit and the filtering continues.

Figure 42-16 shows a moving curtain renewable-media filter. Moving-curtain filters are used in commercial applications to remove lint and aerosols in textile mills, dry cleaners, and press rooms.

Figure 42-16 Rolling curtain renewable media filter.

42.8 ELECTROSTATIC FILTERS

Did you ever notice how electronic components collect dust? The dust is attracted to them because of their electrostatic charge. Electrostatic filters make use of this principle to increase their efficiency. Some disposable filters are manufactured using materials that have an inherent electrostatic charge. However, this charge tends to dissipate as the filter gets dirty, and the filter efficiency declines. Another type of electrostatic filter uses materials that produce static electricity when air flows across the filter. A static electric charge is developed as the air flows over the material, charging the particles. They are then attracted to the media inside the filter. A filter media, such as foam or polyester fibers, is sandwiched in between the statically charged panels (Figure 42-17). These filters typically have a relatively high initial air pressure drop, which increases as they become dirty. These filters must be cleaned monthly to prevent airflow problems.

SERVICE TIP

It is very important to clean electrostatic filters often. It can be very difficult to clean one of these once it has become clogged with dirt. This is especially true of the filters that use a fuzzy-appearing polyester media in the center. Once one of these becomes excessively dirty, it just becomes an expensive disposable filter.

42.9 ELECTRONIC AIR CLEANERS

The operating efficiency of electronic air cleaners varies with airflow. Each model may be used over a range of airflow quantities (CFM). The stated efficiency will be rated at a nominal CFM. The operating efficiency at other airflows within the filter's operating range will be listed separately. Higher airflow produces lower efficiency. Residential electronic air cleaners come in sizes of 800 CFM to 2,000 CFM. Static pressure drop will run about 0.20 in wc at the nominal

Figure 42-17 Composition of electrostatic air filter.

Figure 42-18 The ionization section of an electrostatic air cleaner consists of ionizing wires alternating with grounded plates.

airflow rating point. Ratings are published in accordance with the National Bureau of Standards Dust Spot Test and are certified under AHRI standards. There are three types of units used for commercial service: ionizing plate, charged-media nonionizing, and charged-media ionizing.

Ionizing Plate Air Cleaners

Ionizing plate electronic air cleaners use high-voltage dc current to ionize particles in the air and attract them to oppositely charged plates. A series of thin wires is suspended between a group of grounded plates (Figure 42-18). A high-voltage dc current produces an electric field between negatively charged thin wires with and grounded plates. The dust particles passing through receive a negative charge from the electrical field. This is called the ionizing section because it is ionizing the dust particles. The collection section is a series of plates located just behind the ionizing section. The ionized dust particles are attracted to the oppositely charged collection plates and fasten onto them (Figure 42-19). This process is called two-stage electrostatic precipitation because it occurs in two stages and the dust particles precipitate out of the air.

The voltage is typically 6,000–10,000 V dc. The plates are parallel to the airstream and offer little resistance to the airflow. For best results, the airflow through the plates should be evenly distributed. Conventional-type prefilters are used ahead of the electronic air cleaners to screen out the larger particles in the air (Figure 42-20).

Figure 42-19 Operation of two-stage electrostatic precipitation.

Figure 42-20 The prefilter is seen on the left; the prefilter on the right has been removed.

Figure 42-21 This high-voltage probe and a standard digital multimeter can be used to read the high dc voltage on an electronic air cleaner circuit.

SAFETY TIP

Do not attempt to use a standard multimeter and lead set to measure the output voltage on an electronic air cleaner. The voltage is much higher than either the leads or meter is designed for. The voltage can be read using a special high-voltage probe (Figure 42-21). This probe reduces the voltage to a level that can be safely read by a standard multimeter.

The collector plates must be periodically cleaned, as their efficiency declines as they get dirty. Most collector plates can be removed easily and can be placed in a dishwasher for cleaning. Due to the high voltage used by the electronic units, safety switches are provided that will turn off the power when the filter access door is opened. A few filters have built-in cleaning mechanisms. They use water sprayed on the plates in place. Suitable drains are provided in the bottom of the filter compartment. Ionizing plate air cleaners should be cleaned two to four times a year.

SERVICE TIP

Electronic air cleaners do not make dirt disappear; they collect it. Cleaning the plates is essential. If the plates are allowed to get excessively dirty, arcing can occur between the plates, which burns the dust to a fine white ash. This fine white powdery ash then escapes the air cleaner and can pack in the fins of the indoor coil. Adding an electronic air cleaner and not cleaning it is really worse than using low-efficiency filters.

Charged-Media Nonionizing Air Cleaners

The charged-media nonionizing filters are very different in construction. These filters consist of a dielectric filtering medium, usually arranged in pleats, as in typical extended-surface media filters (Figure 42-22). The dielectric medium consists of glass fiber mat, cellulose mat, or similar material supported by a grid consisting of alternately grounded and charged members. The charged members are supplied with 12,000 V DC power. Airborne particles that approach the field are polarized and drawn to the filaments of the fibers of the media. This type of filter offers about 0.10 in wc resistance to the flow of air when clean, with a face velocity of 250 FPM.

Charged-Media Ionizing Air Cleaners

Charged-media ionizing electronic filters combine the effects of the other two designs. Dust is charged in a corona discharge ionizer and collected on a charged-media filter mat. This construction increases the effectiveness of the filter but is more critical to operate successfully.

SERVICE TIP

The high voltage on an electronic air filter can cause discharges when the surface of the collector plate becomes excessively dirty or if a large particle or insect comes in contact with the collector plate. This electrical discharge or spark can be annoying to homeowners because of its sound and interference with television and radio reception. For installations where persistent arcing is a problem, the source of the arcing must be identified and controlled. It may mean more frequent cleaning of the collector plate or possibly the installation of a prefilter to catch or keep out larger particles or insects.

Figure 42-22 Nonionized charged-media filter operation.

Figure 42-23 Charged particles can cause staining if they escape the electronic air cleaner.

Undesirable Operating Conditions

Two operating conditions that can cause problems with electronic air filters are (1) space charge and (2) ozone. The unit needs to be carefully built and installed so that charged dirt particles do not escape into the filtered space (space charge). If they do, they can darken the walls faster than if no cleaning arrangement was used. Figure 42-23 shows the effects of small ionized particles escaping the air cleaner. Proper installation and application are key to preventing this condition. Moving air at speeds exceeding the filter's rating can allow charged particles to escape.

Electronic air cleaners produce a small amount of ozone because of their high voltage. Ozone is a poisonous gas. When the unit is operating correctly, the amount of ozone produced is well within the recommended safe limits. If the unit is continuously arcing, it may yield levels of ozone, which are annoying and even poisonous. High levels of ozone are indicated by a strong bleach-like odor.

42.10 ADVANCED HYBRID AIR CLEANERS

Several manufacturers now offer air cleaners that clean, sterilize, and deodorize the air. These filters offer some combination of HEPA media filter, ultraviolet light, charged-media electronic air cleaner, and activated charcoal (Figure 42-24). The HEPA filter or electronic air cleaner removes the minute particles, the ultraviolet light or charged media sterilizes the air, and the activated charcoal removes odors. They are aimed at the high-end residential market for customers who are concerned about the indoor air quality of their home.

Figure 42-24 This high-efficiency filter cleans and disinfects the air.

42.11 FILTER INSTALLATION

Filters should be placed ahead of heating and cooling coils and other mechanical equipment to protect the system from dust.

Panel Filters

Panel filters have an arrow that indicates the direction of airflow. It should be pointed toward the unit (see Figure 42-10). The published performance of filters is based on straight-through unrestricted airflow. The filter size should be appropriate for the amount of air passing through it. For example, a panel filter rated for a maximum face velocity of 300 FPM should have a face area of 2.67 ft² for a 2-ton unit: 400 CFM/ton \times 2 tons = 800 CFM, 800 CFM/300 fpm = 2.67 ft², or 384 in². A 20-in \times 20-in filter would work (400 in²); a 16-in \times 20-in would not (320 in²). It is common to pull return air in from both sides of a unit if the airflow capacity requires more filter face area than can be accommodated easily by a single filter (Figure 42-25).

Figure 42-25 Filters can be installed on both sides of a furnace to increase the filter surface area.

Extended-Media Filters

Extended-media filters require the installation of a filter box (Figure 42-26). This box can be mounted to the unit or in the return duct. A transition should be used if the duct size is smaller than the opening in the filter. In either case, sealing the filter box to the duct or the unit is important to maintain maximum filter efficiency. It does not make sense to install an efficient filter and leave air leaks around the filter that will allow dirty, unfiltered air to enter the system. Service access should be considered when installing the filter box. The filters that must come out are as long as the box. It will

Figure 42-26 Medium-efficiency 5-in filters require a filter box.

Figure 42-27 This airflow sensor turns the electronic air cleaner on when it senses airflow.

be difficult to change the filters if a 25-in-wide filter box is installed with a 20-in service access. The filter airflow capacity should match the system airflow.

Electronic Air Cleaners

Electronic air cleaners are installed like extended-media filters, except that they need a power supply. The air cleaner should operate whenever the blower runs, but it should not operate when the blower is off. Some air cleaners have an airflow sensor that detects airflow and automatically turns the filter on and off with airflow (Figure 42-27). Other air cleaners require a relay or sail switch to energize the filter when the fan runs.

42.12 ULTRAVIOLET (UV) LIGHTS

Ultraviolet lights (UV) are used to sterilize the surfaces inside duct systems. These lights have been popular for years in hospitals, where 100 percent of the air entering an operating room has to be outside air. The air passes through a duct box containing a large number of ultraviolet lights, where the air is sterilized before entering the operating room (Figure 42-28). Ultraviolet lights will kill mold, fungus, bacteria, and any other living organisms if the light is intense enough and the organisms are exposed to it for a long enough period of time.

In recent years, ultraviolet light sterilizing units have become available for the residential and light commercial market. Most of the lights used in residential applications are not strong enough to sterilize the air as it passes by. These lights are typically located in the

Figure 42-28 This bio-wall unit can kill viruses and bacteria in the air in one pass. (Courtesy of Sanuvox Technologies, Inc.)

plenum, where they sterilize the coil, drain pan, or filter. Location of the UV light is critical, because UV lights can only disinfect surfaces that the light can see. Typically, more than one lamp is required to adequately cover the coil (Figure 42-29). Lights that are designed to keep the coil, drain pan, or filter clean operate all the time, even when the system is not running. Lights that attempt to sterilize the air come on during system operation. This is accomplished by tying their circuit into the fan blower relay circuit in the indoor equipment.

The intensity of the ultraviolet radiation decreases with use, so the lamps in UV lights require replacement every year in most cases. The effectiveness of the UV light drops off as the lamp nears the end of its useful life. Some longer-life lamps can go 2 to 3 years, but their UV output is typically only half of the original output by the end of 3 years.

SERVICE TIP

Some indoor coil drain pans are made of plastic materials that can be degraded by ultraviolet light. Before installing an ultraviolet light in a plenum or near a coil, make certain that the drain pan is UV resistant.

Figure 42-29 Residential application of UV light to keep the coil clean. (Courtesy of Triatomic Environmental)

SAFETY TIP

Ultraviolet light at the levels required for air sterilization is dangerous to technicians. The ultraviolet light can result in severe skin burns like those caused by too much exposure to the sun. In addition, burns on the eyes can occur. The intensity of the sterilizing lights is such that it only requires a momentary exposure to cause damage. Ultraviolet light boxes must have an interlock circuit that prohibits the light from coming on when access panels are open.

UNIT 42—SUMMARY

Common air contaminants include dust, smoke, biological contaminants, and chemical contaminants. Contaminant particles are measured in microns. A micron is an SI unit of measurement equal to 1/1,000 of a millimeter. Most of the particles in the air are below 1 micron in size. The most common filters use a media that traps the contaminants and lets the air pass through. These filters get more efficient as they get dirty. Filters have a recommended airflow rating that should not be exceeded. A filter's efficiency is stated as its MERV rating. Higher MERV ratings mean higher efficiency filtration. When choosing a filter, it is important to select a filter that has the correct airflow rating and pressure drop for the application as well as a high efficiency. Electronic air cleaners use high dc voltage to attract dust particles to charged media or charged plates. Ultraviolet lights are used to sterilize air-conditioning coils and the inside of system ducts.

WORK ORDERS

Service Ticket 4201

Customer Complaint: Poor Cooling

Equipment Type: Split-System Air Conditioner with a 1-in Electrostatic Air Filter

A customer calls because her unit runs continuously and does not cool. She also has noticed that very little air is coming out of the supply registers. The technician sees that the suction line at the outdoor condensing unit is iced over. Checking inside, the suction line is iced there as well. The filter is a relatively clean electrostatic air filter that the customer bought at the local home improvement store. The technician shows the homeowner the filter packaging, which says the filter's nominal pressure drop is 0.35 in wc when the filter is clean, and explains that her system cannot move enough air with that much pressure drop across the filter. The low airflow caused the coil to freeze over. The technician replaces the filter with a lower efficiency and lower resistance panel filter and leaves the

fan operating without the air conditioner to allow the coil to thaw. Once the coil has thawed out, the airflow returns to normal and the unit operates correctly. The technician advises the customer to consider a 5-in extended-surface media filter if they want a truly high-efficiency filter that will not severely impede the system airflow.

Service Ticket 4202

Customer Complaint: Poor Cooling

Equipment Type: Split-System Air Conditioner with a 1-in Panel Filter

A customer calls because his unit runs continuously and does not cool. He also has noticed that very little air is coming out of the supply registers. The technician sees that the suction line at the outdoor condensing unit is iced over. Checking inside, the suction line is iced there as well. The filter is an inexpensive panel filter that is so dirty that light will not pass through it. The customer is surprised because he remembers changing the filter last year. The technician explains that the panel filters should be changed monthly and recommends cleaning the evaporator coil as well. After cleaning the evaporator coil and replacing the filter, the unit runs properly.

Service Ticket 4203

Customer Complaint: Popping Sound Coming from the System

Equipment Type: Split-System Air Conditioner with an Electronic Air Cleaner

A customer calls because she hears a popping sound coming from her system and is concerned that there may be a loose wire or electrical malfunction. The technician arrives, hears the sound, and realizes that it is coming from the electronic air cleaner. The technician explains that the sound is from the air cleaner arcing due to a large buildup of dirt on the collector plates. The technician removes the cells and places them in the dishwasher to clean while he cleans the prefilter. The technician allows the cells and prefilter to dry, replaces them in the unit, and puts the unit back into operation. The popping sound is now gone.

UNIT 42—REVIEW QUESTIONS

1. How does mechanical filtration work?
2. What is the normal maximum air velocity across the face of a low-efficiency panel filter?
3. How often should a low-efficiency panel filter be changed?
4. How often should a renewable-media pleated surface be changed?
5. What factors should be considered when choosing an air filter?

6. Describe the MERV filter rating system.
7. Why are the highest rated MERV filters not used in residential applications?
8. Why is panel filter media sometimes coated with a viscous substance?
9. What is a HEPA filter?
10. How does increased airflow affect a filter's efficiency?
11. What is the purpose of expanded media area in pleated filters?
12. How does the increased pressure drop across a filter affect system operation?
13. List the three types of electronic air filter units.
14. What is the common operating voltage range on the cells of electronic air cleaners?
15. Describe the operation of an ionizing plate electronic air cleaner.
16. What filter characteristics should be considered when selecting an air filter?
17. Why should a MERV rating always state the air velocity through the filter?
18. How can a high-pressure drop across an air filter adversely affect system performance?
19. What air contaminants are addressed by UV lights?
20. How often do UV lamps need to be replaced?

UNIT 43

Ventilation and Dehumidification

OBJECTIVES

After completing this unit, you will be able to:

1. distinguish between infiltration, exfiltration, ventilation, and exhaust.
2. list the factors that affect building pressure.
3. describe types of ventilation systems.
4. calculate building air changes.
5. discuss the difference between heat-recovery ventilators and energy-recovery ventilators.
6. explain the benefits of dehumidification.
7. discuss the methods of dehumidification.
8. list types of dehumidifiers.

43.1 INTRODUCTION

Ventilation and dehumidification are necessary for a complete comfort system. A total comfort system controls more than temperature. Controlling the amount of air entering the building and the humidity in the building are also important aspects of comfort. This is especially true of today's tight buildings that have limited infiltration. Sealing up the building increases energy efficiency but reduces the air changes to a level where odors and stuffiness can be a problem. Ventilation provides a solution to this problem. Unlike infiltration, ventilation can be controlled. Dehumidification is always important in humid climates like the southeast, but it is especially important with tighter building construction. Normal living activities such as cooking, bathing, and washing produce moisture. Dehumidification keeps the moisture buildup inside the house from becoming hazardous to the building and its occupants.

43.2 BUILDING AIRFLOW

Air is constantly moving in or out of most buildings. Some of this air leaks in or out of the building, and some of the air is drawn in or exhausted out by ventilation equipment. Air that leaks in is called infiltration; air that leaks out is called exfiltration (Figure 43-1). The amount of infiltration or exfiltration is affected by building construction, wind velocity, inside combustion appliances, and building pressure. Ventilation and exhaust are the intentional movement of air in or out of the building with fans. Ventilation refers to blowing air in, while exhaust refers to blowing air out (Figure 43-2). Of course, you cannot blow air into the building without letting some of the air that is already in the building leave. Similarly, exhaust fans cannot work if there is no source of makeup air coming in. Makeup air is air that is drawn in to replace air that is exhausted out. In small residential applications like bathroom exhaust fans, the assumption is made that there is enough infiltration to provide makeup air. In larger commercial applications, this simply won't work.

Figure 43-1 Air leaking in is infiltration; air leaking out is exfiltration.

TECH TIP

Many people are not aware of the necessity for makeup air for exhaust systems. Often, problems with an exhaust system not operating properly can be traced to an inoperative makeup-air blower or a blocked makeup-air duct.

43.3 AIR CHANGES

Replacing all the air in a building with air from outside is called an air change. It means that all the air inside has been changed for new air from outside. The amount of infiltration a building has, or the amount of ventilation required, is stated

Figure 43-2 Ventilation fans blow air into a building; exhaust fans blow air out of a building.

in air changes per hour. One air change an hour means that it takes an hour for all the air in the building to be replaced with air from the outside. The average air change rate for existing homes is between one and two air changes per hour. However, new homes built today usually have an air change rate between one half to one air change per hour. Extremely tight new construction can achieve air change rates as low as one third air change per hour. Homes with such low air change rates need some form of mechanical ventilation to bring in fresh outside air in to compensate. Commercial buildings use mechanical ventilation to achieve much higher air change rates. The higher air change rates are necessary due to the increased number of occupants and processes giving off carbon dioxide, water, and fumes. Figure 43-3 shows typical air change rates for different commercial applications.

The amount of airflow in cubic feet per minute (CFM) required to produce one air change per hour can be calculated by dividing the building volume by 60:

$$\text{Air change CFM} = (\text{floor area} \times \text{ceiling height}) / 60$$

Multiply this number times the number of air changes required to get the total ventilation CFM required:

$$\text{Total ventilation CFM} = \text{Air change CFM} \times \text{required air changes}$$

RECOMMENDED AIR CHANGES PER HOUR

These two formulas can be combined:

$$\text{Total ventilation CFM} = (\text{floor area} \times \text{ceiling height} \times \text{air changes}) / 60$$

43.4 INFILTRATION MEASUREMENTS

The only truly accurate method of measuring building infiltration is to pressurize the building with a large fan and measure the airflow required to maintain that pressure. The amount of air required to maintain that pressure provides a reference point in describing the infiltration rate of a structure. This measurement can be accomplished with a blower door (Figure 43-4). A blower door contains a large fan, a manometer for measuring the building pressure, and an airflow gauge to measure the amount of air required to maintain a particular pressure. It is installed in an exterior door, the house is pressurized, and the CFM required to maintain that pressure is read.

GREEN TIP

Blower door readings are useful when performing house tightening. They provide an objective measurement of the degree of improvement achieved.

Figure 43-4 Blower door in operation. (Courtesy of BuilderFish)

43.5 WHY VENTILATE?

Air that enters a building through infiltration is uncontrolled. It cannot be cleaned, heated, cooled, or dehumidified before it enters the building. The location and amount of infiltration is also largely outside of our control. In the winter, infiltration around windows and doors creates a draft. This increases the heat load and decreases comfort. On the other hand, ventilation air can be controlled. We can control the amount of air entering the building and we can condition it before it enters the occupied space, eliminating drafts. In commercial buildings with many occupants, ventilation provides fresh air and prevents the buildup of carbon dioxide inside the building. Ventilation can also dilute odors and contaminants produced inside the building by people, machines, or processes. Exhaust systems can be located at the source of contaminants and carry them out of the building before they can escape into the rest of the building. Many builders have started to use tighter construction techniques such as sealing penetrations, foaming around windows and doors, and using housewrap. This helps reduce drafts and heat loss but increases stuffiness and odors. Ventilation is really necessary in extremely tightly constructed buildings. Ventilation and exhaust are used to gain control over the air entering and leaving the building and to control building pressure.

43.6 BUILDING PRESSURE

You probably don't think of a building as having a pressure, just as you seldom notice the atmospheric pressure. It is not unusual for the air pressure in a building to be a little lower or higher than the outside air pressure. Air comes through cracks in the walls whenever there is a pressure

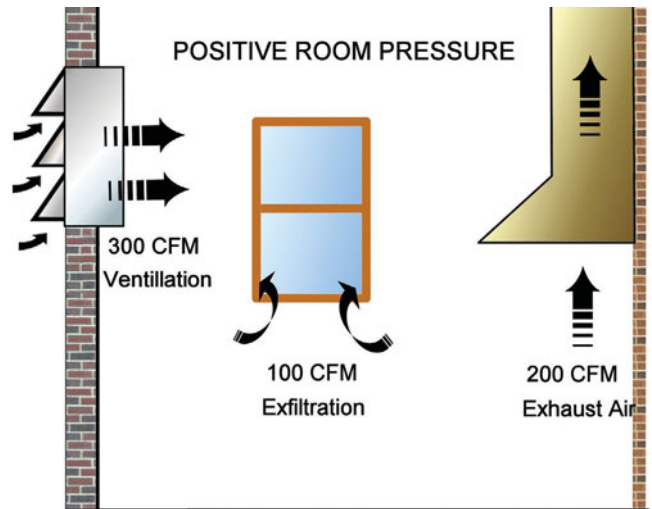

Figure 43-5 Illustration showing positive building pressure.

difference between inside and outside. Commercial structures normally try to maintain a pressure slightly above the outside air pressure, called a positive pressure. Buildings with a positive pressure will experience exfiltration rather than infiltration. This improves overall comfort by reducing drafts. Ventilation is needed to maintain a building at a positive pressure. A positive pressure is created when more air enters the building through ventilation than leaves through exhaust. Pressure builds and the remaining air is forced out through exfiltration (Figure 43-5). A negative pressure is created when the exhaust air exceeds ventilation air. A negative pressure is created and the difference is made up through infiltration (Figure 43-6). Factors that reduce building pressure include any exhaust system, all combustion appliances, and leaks in supply air ducts located in unconditioned space (Figure 43-7). Leaky ductwork is a major contributor to negative building pressure in many older residential systems. Air that leaks out of the supply duct system in unconditioned space can equal all the air leaking through the rest of the structure.

Figure 43-6 Illustration showing negative building pressure.

Figure 43-7 Factors affecting building pressure.

SAFETY TIP

Combustion appliances should not be located in negative pressure areas. This is why the return air should not be located in the same room as the furnace. The furnace blower can lower the pressure in the equipment room to the point that the vent does not operate correctly and combustion products spill out into the room. This sets up the possibility of circulating combustion products, including carbon monoxide, throughout the house.

Factors that increase building pressure are ventilation systems and leaks in return-air ducts located in unconditioned space. The pressure within a building can vary from room to room. A room with a large return air grille and no supply registers can be negative, while a room next to it with a large supply register and no returns is positive. The pressure difference between inside and outside, or between two rooms, can most easily be measured using a sensitive digital manometer that can read absolute pressure in inches of water or pascals (Figure 43-8).

43.7 TYPES OF VENTILATION AND EXHAUST SYSTEMS

Ventilation systems grouped by their effect on the building are as follows:

- Exhaust: negative pressure (see Figure 43-6)
- Supply: positive pressure (see Figure 43-5)
- Balanced: neutral pressure (Figure 43-9)

An exhaust system uses a fan to force exhaust air out and relies on infiltration or makeup air ducts to supply air from outside. This type of system creates a negative pressure in the entire building so that outside air is sucked in. An example would be an attic fan in a house that sucks air out of the house and blows it into a ventilated attic (Figure 43-10). The entire house is under a negative pressure while the attic becomes pressurized.

Figure 43-8 This digital manometer can read the absolute pressure in a room. (Courtesy of Testo, Inc.)

Figure 43-9 Illustration of balanced ventilation system.

Figure 43-10 A whole-house attic fan works by drawing in air through open windows and expelling it through the attic vents.

A supply system blows air into the building and relies on exfiltration and exhaust vents to carry air out of the building. A makeup-air blower in a mechanical room with a large number of combustion appliances would be an example. The mechanical room becomes a positive pressure, aiding in combustion and ventilation.

A balanced pressure system typically uses fans to blow air both into and out of the building. This prevents the ventilation system from affecting the building pressure either way. A slight positive pressure can be maintained with a balanced system by controlling the amount of air leaving compared to the air entering. One advantage of using blowers for both the ventilation and exhaust air is that you have more control. Another advantage of a balanced system is that heat-recovery or energy-recovery ventilators can be used to recover much of the heat from the exhaust air before it leaves, increasing the overall system efficiency.

43.8 HEAT- AND ENERGY-RECOVERY VENTILATORS

A heat-recovery ventilator uses a supply-air blower to move ventilation air in and an exhaust-air blower to move exhaust air out. The two air streams pass through a heat exchanger core that exchanges heat between them (Figure 43-11). A heat-recovery ventilator transfers only sensible heat due to temperature difference. An energy-recovery ventilator uses desiccants to transfer both sensible and latent heat. The desiccant transfers moisture between the supply air and the exhaust air. This is desirable in the summer in humid climates where controlling humidity is as important as controlling temperature. The energy-recovery ventilators are not recommended in colder climates where operation

below 25°F for several hours is likely. In colder climates, heat-recovery ventilators should be used instead. Heat-recovery ventilators are available with a defrost feature for very cold climates. When the incoming air is below 23°F, the unit goes into defrost. During the defrost cycle, the incoming outdoor air is shut off by either a motorized damper or by simply shutting off the supply-air blower. Warm air from the house is circulated through the unit until the incoming side of the heat exchanger heats up.

GREEN TIP

Heat and energy-recovery ventilation systems save energy by transferring up to 80 percent of the energy between the ventilation air and the exhaust air while reducing infiltration.

The core in a heat-recovery unit is the part that actually exchanges the heat. There are several different types of heat-recovery cores used in energy-recovery ventilators, including flat plate, rotary wheel, and heat pipe. Flat-plate cores are the most common. They consist of several thin plates spaced about 1/8 in apart. The plates are connected at the ends and edges so the incoming outdoor airstream and the leaving indoor airstream can move through the alternating spaces staying separate from each other (Figure 43-12). Flat-plate cores can be made of plastic, aluminum, or treated paper.

Rotary-wheel cores use a rotating wheel made out of a corrugated plastic material that forms thousands of honeycomb air passages. Heat wheels can be from 1 to 10 ft in

Figure 43-11 Illustration of heat-recovery ventilator operation.

Figure 43-12 Flat-plate heat exchanger used in heat-recovery cores.

Figure 43-13 Heat-recovery ventilation unit using a heat wheel.

diameter and 6 to 30 in thick. The wheel is mounted with half of the wheel in the exhaust air duct and half in the supply air duct (Figure 43-13). The wheel rotates slowly: one to twenty rounds per minute. The warmer air transfers heat to the wheel, the wheel rotates to the cooler air, and the heat is transferred from the wheel to the cooler air.

A heat pipe is a miniature refrigeration system in a closed tube. A heat pipe is essentially a closed tube installed on a slant with a refrigerant sealed inside. When one side is heated, liquid boils and absorbs heat. The gas rises and goes to the other side because of its lighter density. The gas then condenses on the cool side, giving off

Figure 43-14 Illustration of heat-pipe operation.

the heat. The condensed liquid flows back to the warm side by gravity (Figure 43-14). Heat pipes can be installed so that they transfer heat from one airstream to another (Figure 43-15).

Heat-recovery ventilators and energy-recovery ventilators are rated by either sensible recovery efficiency or apparent sensible effectiveness. The sensible recovery efficiency is found by dividing the temperature rise of the outdoor air by the temperature difference between the two airstreams. For example, with 40°F outdoor air, 70° indoor air, and 60°F fresh air entering the house, the sensible recovery efficiency would be $(60 - 40)/(70 - 40) = 0.67$, or 67%. "Apparent sensible effectiveness" is the term used in CSA standard C439M for testing heat-recovery ventilators. This measurement takes into account other variables, including motor heat gain, cross-leakage gain, and casing gain. It is usually numerically higher than the sensible recovery efficiency of the HRV.

43.9 WHY DEHUMIDIFY?

In humid climates such as the Southeast, removing humidity from the air in warm weather is just as important to comfort as reducing temperature. Being warm-blooded, our body normally produces more heat than needed and then regulates our temperature using different cooling mechanisms. The primary cooling mechanism is evaporation of perspiration from our skin. Dry air makes us feel cooler because it accelerates the evaporation from

Figure 43-15 Heat pipes installed on an air-conditioner coil.

our skin. Humid air makes us feel warmer because the evaporation process is slower. Dehumidification can be the difference between being comfortable at 78°F and being uncomfortable. Dehumidification can save energy by reducing the amount of sensible cooling required for comfort. Many people with oversized air-conditioning systems essentially overcool their house to be comfortable because their systems do not run long enough in mild weather to reduce humidity, so they do not feel comfortable until they reach temperatures of 70°F in their house. Humidity represents heat because of the latent heat contained in the water vapor. When adding outdoor ventilation air during the cooling season, humid air adds to the heat load on the air-conditioning system.

43.10 AIR CONDITIONING AND DEHUMIDIFICATION

Air-conditioning units are the most common form of dehumidification. The air conditioner's evaporator coil typically operates below the dew point of the air flowing over it, causing water to condense on the coil. This is why air conditioners require a drain. However, there are some limitations on an air conditioner's ability to dehumidify. It takes several minutes for most air-conditioning coils to get cold enough to sweat. An oversized system will often not operate below the dew point for very long before satisfying the thermostat. Since air conditioners are sized for conditions that only occur a small percentage of the time, most air conditioners are oversized most of the time. The key to dehumidifying with an air conditioner is long run times and slow evaporator air flow. A properly sized air-conditioning system will run longer, allowing longer operation with an evaporator operating below the dew point. Systems with ECM blowers and thermidstat controllers have a special dehumidification mode that reduces system airflow for dehumidification (Figure 43-16). This increases the latent system capacity and decreases its sensible capacity. Two-stage cooling systems can help by allowing longer system operation at moderate loads. All of these are a big improvement over the typical oversized single-capacity system with a PSC blower. However, an air conditioner is still not a dehumidifier.

Figure 43-16 Dehum terminal on thermidstat and blower board.

GREEN TIP

Using a whole-house dehumidifier with an air-conditioning system can decrease overall energy use. The dehumidifier takes care of the latent load, allowing the air conditioning load to be mostly sensible cooling. The lower relative humidity allows for a higher thermostat setting, reducing the run time on the air conditioner. When the air conditioner does operate, it is performing mainly sensible cooling. Air-conditioning systems are more energy efficient when providing sensible cooling.

43.11 REHEAT SYSTEMS

The primary problem with using air conditioning for dehumidification is what to do when you need to dehumidify but you do not need to cool? While air conditioners do remove water from the air, the air leaving an air conditioner actually has a very high relative humidity. It was cooled to the dew point to remove the water, so it is near 100 percent relative humidity when it leaves the air conditioner. If you need dry air to blow directly on something to dry it out, air-conditioned air is not a good choice. Many commercial systems use reheat to solve this problem. Reheat refers to reheating the air after it has been air-conditioned. The air is cooled to the dew point to dehumidify it and then reheated to offset the undesired effect of overcooling. The air leaves with a lower relative humidity. While very effective, reheat systems are energy hogs. You literally are operating the heating and cooling at the same time. The energy impact can be mitigated if the reheat comes from the hot discharge gas coming out of the compressor. Units that use hot-gas reheat during dehumidification use a solenoid-operated three-way valve to direct hot gas to the reheat coil (Figure 43-17). Electric-strip heat can also be used for reheat, but it is more expensive to operate. The main advantage to electric reheat is the system's simplicity.

Reheat systems typically are controlled by both a thermostat and a humidistat. The air conditioner will operate if either the temperature or the humidity is too high. The heat will operate whenever the temperature is too low. If the humidistat turns on the air conditioner and the temperature drops below the thermostat heating setpoint, the reheat will energize.

Figure 43-17 Reheat valve and coil on unit with hot-gas reheat dehumidification.

43.12 HEAT PIPES

Heat pipes do not use any energy; they work entirely by temperature difference. A heat-pipe system used to enhance coil dehumidification has one part before the evaporator coil and another after the evaporator coil (see Figure 43-15). Heat pipes improve an air conditioning system's ability to dehumidify by transferring some heat from the air entering the evaporator coil to the air leaving the evaporator coil. They cool the air before it enters the evaporator, so that the evaporator operates at a lower temperature, increasing the dehumidification effect of the coil. The heat that was removed from the air entering the coil is added back to the air leaving the evaporator. In effect, the air is reheated using heat taken from the air itself. Coils that combine the evaporator and heat pipe coils into a single unit make applying the heat pipe easier.

TECH TIP

Heat pipes help improve the dehumidification properties of an air-conditioning coil, increasing the latent cooling capacity and decreasing the sensible cooling capacity. This causes longer operating cycles. Although heat pipes do not use any energy to operate, they do add to the operating cost of the air conditioner by reducing the sensible capacity and extending the operating time.

43.13 DEHUMIDIFIER FUNDAMENTALS

Basically, a compression-cycle dehumidifier is an air conditioner with a single blower that moves air first over the evaporator and then over the condenser. The air first passes over the evaporator, where it is cooled to the dew point to remove water, and then the same air passes over the condenser, where it is reheated to a temperature slightly above its original temperature because of the heat of the compressor and fan motor (Figure 43-18). Thus, the dehumidifier

Figure 43-18 Basic dehumidifier operation.

reduces both the amount of water in the air and the relative humidity of the leaving air.

Dehumidifier capacity is listed in pints per day. This represents the amount of water the unit can remove operating continuously for 24 hours at design conditions. ANSI/AHAM DH-1-2003 standard conditions are 60 percent RH, 80°F. Dehumidifier capacity drops as either the air temperature or the relative humidity drops. The capacity can drop by as much as 50 percent when operated at more moderate conditions, such as 70°F and 50 percent RH. Dehumidifier energy use is rated in liters of water per kilowatt-hour of energy use (L/kWh), called the energy factor. Larger capacity dehumidifiers tend to be more energy efficient than smaller ones. The energy factor ranges from around 1.0 for a small, inefficient console model to 3.5 for a more efficient, larger whole-house model.

43.14 CONSOLE DEHUMIDIFIERS

Console dehumidifiers are small plug-in electrical appliances that sit in the room they are conditioning. They have capacities ranging from 20–70 pints per day. Console dehumidifiers have a compressor and a fan motor. The compressor is controlled by a humidistat, which cycles it on and off to maintain the humidity setting. The humidistat can be either a mechanical switch controlled by an element that expands and contracts with different humidity levels or an electronic sensor that changes capacitance with different humidity levels (Figure 43-19). The fan motor runs all the time on many models but can cycle with the compressor in some models. Figure 43-18 shows the parts of a typical console dehumidifier. The evaporator is designed to operate just above freezing to maximize dehumidification. When the entering air temperature is below 65°F, the evaporator coil temperature can drop below freezing, and frost will start to form (Figure 43-20). Frost buildup will impede airflow and reduce the unit's effectiveness. Continuing to operate with a frozen evaporator can damage the compressor. A frost-sensing switch shuts off the compressor when the evaporator coil starts to frost (Figure 43-21). The fan continues to operate.

Water from the evaporator coil drains into a plastic bucket that is tilted slightly so that it presses against a switch (Figure 43-22). The switch opens and shuts off the system when the bucket is full. A console unit operated in a basement will typically need to be emptied twice a day.

Figure 43-19 Mechanical and electronic humidistats.

Figure 43-20 Frost on dehumidifier evaporator coil.

Figure 43-21 Frost-sensing switch.

Figure 43-22 Condensate bucket and fill switch.

Figure 43-23 Hose connected to back of bucket.

Most units have provisions for attaching a garden hose to the bucket so that the water can be run to the outside or into a floor drain (Figure 43-23). This eliminates the need to empty the bucket.

Console dehumidifiers do have some drawbacks, including relatively low capacity, noise, and the inconvenience of emptying the bucket. These are all related to their design: a small plug-in appliance that sits in the room. They are typically noisy because of the compressor.

43.15 WHOLE-HOUSE DEHUMIDIFIERS

Several companies now offer whole-house dehumidifiers that can be integrated into a complete comfort system for your house. Like the console units, they consist of a complete refrigeration system that has a single airflow over the evaporator and condenser coils (Figure 43-24). Whole-house systems offer many advantages over small console units, including higher capacity, higher energy efficiency, filtration, and ventilation. They have a blower that is strong enough to move air through ductwork, allowing them to be integrated into the heating and cooling system

Figure 43-24 Parts in a whole-house dehumidifier.

Figure 43-25 Whole-house dehumidifier connected to system ducts. (Courtesy of Therma-Stor, LLC)

Figure 43-26 Whole-house dehumidifier operating as a standalone unit. (Courtesy of Basement Systems)

ductwork (Figure 43-25). They can also operate as a standalone unit (Figure 43-26). Even when operated as a standalone unit, whole-house systems do not have to be located in the space they are conditioning because they can be connected to ductwork. Most whole-house dehumidifiers also offer high-efficiency air filtering, with filters ranging from MERV 8 to MERV 14. This is especially important when using a model that adds outdoor ventilation. A whole-house dehumidifier with outdoor ventilation and a high-efficiency filter can make a significant improvement to the indoor air quality of most houses.

43.16 DESICCANT WHEEL DEHUMIDIFIERS

A desiccant is a chemical that adsorbs water vapor by chemical attraction. Desiccants will adsorb water vapor from the air. When the desiccants are heated, they release this water

Figure 43-27 Close-up of heat wheel material.

vapor. Desiccants are used in filter driers and in the little bags packed in electronic equipment to keep it dry during storage and shipping. A desiccant wheel dehumidifier uses desiccants imbedded in a rotating wheel made out of a corrugated plastic material. The corrugated material forms thousands of honeycomb air passages (Figure 43-27). The wheel rotates very slowly: ten to twenty rounds per hour. Two separate airstreams pass through the wheel. One airstream is the air to be dehumidified, and the other is the regenerating air. As the wheel turns, the desiccant passes first through the incoming air, where the desiccant adsorbs moisture from the air. Next, the desiccant passes through a regenerating zone, where the desiccant is dried by the hot regenerating air. The wheel continues to rotate and the adsorbent process is repeated. Typically, about three-fourths of the desiccant wheel is exposed to the incoming air throughout the process. The regeneration heat source can be a direct-fired gas burner, a hot water or steam coil, condenser air, or hot exhaust air. Figure 43-28 shows a typical desiccant wheel dehumidifier. Desiccant wheel dehumidifiers are generally designed for large commercial applications. One advantage desiccant drying has over refrigerated drying is that desiccant systems can operate at temperatures below freezing. There are a number of specialized systems that incorporate desiccant wheels along with refrigeration to meet the needs

Figure 43-28 Illustration of how a desiccant wheel dehumidifier works.

of a particular application. Figure 43-29 shows a unit made specifically for conditioning ice-skating rinks.

UNIT 43—SUMMARY

Infiltration is the process of air leaking into a building; exfiltration is air leaking out of a building. Ventilation air blows into a building; exhaust air blows out. Building pressure becomes positive when ventilation air exceeds exhaust air. Building pressure becomes negative when exhaust air exceeds ventilation air. Ventilation systems can be grouped by building pressure as exhaust (negative pressure), supply (positive pressure), or balanced (neutral). Heat-recovery ventilators transfer heat between exhaust air and ventilation air to reduce the energy lost in the exhaust air. Energy-recovery ventilators use desiccant to transfer both temperature and humidity. The types of heat-exchange cores used in heat-recovery ventilators include flat plate, rotary wheel, and heat pipe.

Dehumidification can be as important as temperature reduction for maintaining comfort in humid areas. Dehumidification can be accomplished through air conditioning, air conditioning with reheat, or dedicated dehumidifiers. Dehumidifying with an air conditioner is more effective with long run times and slow evaporator air flow. The air leaving an air conditioner is at a high relative humidity because it has been cooled to the dew point. Reheating the air-conditioned air lowers the relative humidity. Reheat systems are generally not energy efficient. A dehumidifier is an air conditioner with a single blower that moves air first over the evaporator and then over the condenser. The air is cooled to the dew point by the evaporator, water is removed, and then the air is heated back up by the condenser. Dehumidifiers are available as console units, whole-house systems, or large commercial systems. Large commercial dehumidifiers typically use desiccant wheels. The desiccant in the wheel adsorbs moisture from one airstream and releases it to a heated, regenerating airstream.

WORK ORDERS

Service Ticket 4301

Customer Complaint: Exhaust Vent Not Working Properly

Equipment Type: Commercial Exhaust Hood

A technician is called to check the operation of a commercial exhaust hood. A new restaurant has just opened in an older part of downtown in an old retail store that has been converted into a restaurant. The technician notices that the door, which swings out, is hard to open and then slams shut behind him. The manager shows the technician the hood and complains that even though it is new, it does not seem to work. The kitchen is filled with smoke. The technician asks who installed it, and the manager admits that he did it himself to save money. He bought the hood over the Internet. The technician asks where the makeup-air duct is, and the manager looks puzzled. The technician explains that to exhaust air out, you have to bring air in to replace it. To illustrate, he props open the door and shows the manager that the fan operation is improved. He suggests that the manager make an appointment with one of the company engineers to determine if the hood is properly sized and suggest a solution, including installing makeup-air ducts.

Service Ticket 4302

Customer Complaint: Stale Air Inside House

Equipment Type: High-Efficiency Heat Pump Installed in a Super-Insulated House

A technician is called to take a look at a system in a new, super-insulated house. The system appears to be operating well—the temperature stays at the thermostat setpoint. However, the homeowners complain that the house just feels stuffy. They cooked fish last night and the technician can still smell it this afternoon. The technician notes that the house appears to be very tight. The homeowner proudly states that the people who did the blower door test said they had never seen a house with this low a leakage rate. The technician suggests bringing in outside ventilation air. The homeowner asks if that is not defeating the purpose of sealing up the house. The technician explains that they would use a heat-recovery ventilator that exchanges heat between the exhaust air and the incoming ventilation air. This allows controlled ventilation without incurring an energy cost to reheat the incoming ventilation air.

Service Ticket 4303

Customer Complaint: Musty Odor in Finished Basement

A technician is called about a musty odor in the basement. The owners have read about dirty sock syndrome and feel that they may need an epoxy coated coil. The

technician asks if the smell is everywhere or just in the basement. They say mainly in the basement. The technician suggests that the problem may be high relative humidity in the basement. The technician measures the humidity with his electronic hygrometer and measures 70 percent relative humidity. He explains that anything over 60 percent will foster mold and mildew growth and suggests a dehumidifier. They say that they saw one at the drugstore for \$300. He suggests that they may need a larger unit and offers to have a salesman come and provide a free estimate of the size and type of equipment that would best solve their problem.

Service Ticket 4304

Customer Complaint: Underground House Feels Sticky

A technician is called to look at an earth-bermed underground house. Even though the house has no air-conditioning system, the temperature inside is only 76°F compared to 90°F outside. However, the homeowners say they still feel warm. The technician measures the humidity and finds that the relative humidity is 65 percent. He explains that the high humidity makes the body feel warmer. He suggests a whole-house dehumidifier that would connect to the existing furnace ducts. The technician explains that dehumidification would make the house feel cooler.

UNIT 43—REVIEW QUESTIONS

- What is the difference between infiltration and exfiltration?
- What is the difference between exhaust air and ventilation air?
- What benefit is there to supplying fresh air through ventilation versus simply allowing fresh air to come in through infiltration?
- What is makeup air?
- How does a building end up with a positive or negative pressure?
- Explain how a balanced ventilation system works.
- Explain how a heat-recovery ventilation system works.
- What is the difference between a heat-recovery ventilation system and an energy-recovery ventilation system?
- How can a building's infiltration rate be accurately measured?
- How can building pressure be accurately measured?
- Why does the humidity in the air affect comfort?
- How does the humidity in the air affect the load on an air-conditioning unit?
- Explain how a reheat system operates.
- Explain how a heat pipe works.
- How can heat pipes be used to improve the dehumidification abilities of air-conditioning systems?
- Describe how a basic compression-cycle dehumidifier works.
- Describe the energy-efficiency ratings used for dehumidifiers.
- Describe the system for rating dehumidifier capacity.
- What effect do ambient temperature and relative humidity have on dehumidifier capacity?
- How do console dehumidifiers keep from being blocked with frost when operating at temperatures below 65°F?
- Which type of dehumidifier is generally more efficient: small console units or larger whole-house units?
- What advantages do whole-house dehumidifiers have over small console units?
- Explain how a desiccant wheel dehumidifier works.
- What types of dehumidifiers are used on large commercial applications?
- What advantage do desiccant dehumidifiers have over refrigerated dehumidifiers?
- What is the CFM requirement for a ventilation system to provide 1.5 air changes per hour in an 1,800 ft² house with a 10 ft ceiling?
- What is an air change?
- Why do commercial buildings require more air changes per hour than a residential house?

UNIT 44

Residential Air Conditioning

OBJECTIVES

After completing this unit, you will be able to:

1. explain the details of a unitary refrigeration system.
2. install a room or window air conditioner.
3. describe how a residential split air conditioning system is configured.
4. explain why split systems were developed.
5. discuss the proper arrangement and placement of equipment in a split system.
6. inspect and change air filters.

44.1 INTRODUCTION

Residential air conditioning generally includes single family, multifamily, and low-rise multifamily private household residences. The air-conditioning type is typically central forced air, central hydronic, or zoned. The capacities of residential installations typically range from less than 1 ton up to about 5 tons.

44.2 UNITARY SYSTEMS

Residential air-conditioning systems are often made up of unitary air-conditioning components. These are factory built and tested systems, complete as much as possible, with piping, controls, wiring, and refrigerant. Self-contained package units are usually simple to install, requiring only service connections and in some cases ductwork for field applications. The simplest of these is the window-mounted room air conditioner.

Unitary air-conditioning equipment consists of one or more factory-made assemblies, which normally include an evaporator or cooling coil, a compressor and condenser combination, and possibly a heating unit. When the air conditioner is connected to a remote condensing unit, such as in residential applications, the system is often referred to as a split system. A split-system installation will require more fieldwork for the technician as compared to the installation of a simple package unit. The sizes of unitary equipment range from small fractional-tonnage room coolers to large packaged rooftop units in the 100-ton category. Split-system equipment up to 5 tons in capacity may be classified as either commercial or residential. There is a wide range of applications in both markets using the same product; however, above 5 tons the application becomes distinctly commercial, and product designs use different components.

44.3 ROOM AIR CONDITIONERS

Room air conditioners were primarily developed to provide a simplified means of adding air conditioning to an existing room. These units are considered semiportable in that they can easily be moved from one room to another or from one building to another. They provide cooling, dehumidifying,

Figure 44-1 Window air-conditioning unit for cooling.

filtering, and ventilation, and some units provide supplementary heating.

In numbers sold, room air conditioners such as the one shown in Figure 44-1 outsell all other types of unitary equipment. They are relatively low in cost, easy to install, and can be used in almost any type of structure, as shown in Figure 44-2.

Figure 44-2 Window air-conditioning unit on the Harry Elkins Widener building at Harvard University.

The disadvantage of room air conditioners is that they may either block part of the window area and prevent the window from being opened or require a special hole through the wall. Some people object to the operating noise that they produce close to the occupants. They are best used to condition a single room, but the spillover can supply some conditioning to adjacent areas.

TECH TIP

A common problem with window air-conditioning units is the nuisance trips of the residence circuit breakers. Window units are often used in older homes where the electrical service is not adequate for the air-conditioner load. It may be possible to rewire the residence for a single circuit to the air conditioner, or it may be best to downsize the system to one that will not trip the circuit breaker. Downsizing the unit may provide less than desired levels of cooling on extremely hot days. However, the constant shutting down of the oversized unit electrical service can result in the same lack of cooling. In addition, it may be possible to use more than one window unit in a room if the electrical outlets in that room are serviced by more than one circuit breaker.

44.4 CONSTRUCTION AND INSTALLATION OF ROOM AIR CONDITIONERS

There are basically two parts to the unit, as shown in Figure 44-3. One section goes inside the room, where the evaporator fan draws in room air through the filter and cooling coil, delivering conditioned air back into the room. The other section extends outside the room, where the condenser fan forces outside air through the condenser, exhausting the heat absorbed by the evaporator. One motor operates both the indoor blower and outdoor fan (Figure 44-4). The motor shaft extends through the separating partition and drives both fans. Condensate from the evaporator coil flows into the drain pan, which extends below the condenser fan. The condenser fan tip dips into condensate, splashing it onto the hot condenser, where it evaporates and is blown into the outside air.

The window-mounted units are supplied with a kit of parts for installation. Sill brackets, window mounting strips, and sealing strips are set in place for installations in double-hung windows (Figure 44-5). Side curtains fold out to fill up the extra window space (Figure 44-6). A sponge rubber seal is provided for the opening where the sash overlaps, and a sash bracket is installed to lock the lower sash in place (Figure 44-7).

Room air conditioners are also available in a vertical configuration for mounting in sliding window openings (Figure 44-8). These vertical conditioners are held in place by the sides as opposed to the conventional-shaped room air conditioners that are secured in place on their tops and bottoms.

Installation Precautions

Be sure to plan the installation, even if you feel it will be simple! Very often there will be furniture in the way of the

Figure 44-3 Two basic parts of a window unit.

window. Ask for permission to move the furniture or have the customer clear the space. Drilling and mounting the unit will be somewhat messy. Warn the customer of this ahead of time. Place a drop cloth on the floor and then always remember to clean up any mess when you are finished with the job.

There are also a number of safety concerns that must be addressed. Some units are quite heavy and can easily be dropped from a high-story window during installation. Many units have sharp corners and are very slippery, so a good pair of gloves will help. Grabbing onto the tubing for a better hold will ruin the new unit before it is even installed. Don't drill through the tubing when installing the cabinet with the chassis inside. Make sure that the supporting bracket is installed properly and in place before aligning the unit. If the unit is too heavy, then get some additional help. When lifting the unit with another person, keep it level. The taller person will tend to tip the unit and the drain pan of water will spill all over you and the customer's floor.

44.5 EER AND SEER RATINGS

The typical size range for window air conditioning units is from 5,000 to 20,000 BTU/hr. These ratings are based on inside air at 80°F db temperature 67°F wb temperature, and outside air at 95°F db temperature. Smaller units normally operate on 115 V, while larger models operate on 230/208 V.

Equipment is generally rated for efficiency by the manufacturer to help determine which system is most suitable for a particular application. This energy efficiency ratio (EER)

Figure 44-4 Refrigeration cycle of a room cooler.

is calculated by taking the output in BTU/hr and dividing it by the input in watts. The higher the EER rating, the better the efficiency.

The seasonal energy efficiency ratio (SEER) takes into account the cycling of the equipment on and off and is generally considered to be a better indicator of actual equipment efficiency. The Air Conditioning, Heating and Refrigeration Institute (AHRI) rates and publishes these ratings.

44.6 CONSOLE THROUGH-THE-WALL CONDITIONERS

A console through-the-wall conditioner is a type of room cooler that is designed for permanent installation. It was developed to provide individual room conditioning for hotels, motels, offices, and low-rise multifamily private household residences where it is impractical or uneconomical to install a central plant system. An opening needs to be made in the outside wall adjacent to the unit

for condenser air and ventilation. These units are also known as packaged terminal air conditioners (PTAC), as shown in Figure 44-9.

TECH TIP

PTACs are most commonly used in hotels, nursing homes, apartment complexes, and other such areas where the area being cooled is limited. PTAC units may be straight air conditioning, heat pumps, heat pumps with electric resistance supplemental heating, or straight air conditioning with electric resistance heating. All of these units are similar in appearance, and most fit in a standard wall sleeve. These units are accessible from inside the occupied space, and in most cases the condensate is simply allowed to drain outside the building. Some cities and municipalities have ordinances controlling condensate from PTAC units, but many do not.

Figure 44-5 Installation diagram of a room cooler showing the supporting bracket from the outside.

Performance

PTAC sizes range from 6,800 to 14,900 BTU/hr at standard rating conditions. The quantity of outside air that the units can admit ranges from 40 to 55 CFM depending on the size of the unit. Units are available for 115 and 208/230 V, single-phase, ac power. Electric heat capacity from 1.5 to 5.0 kW

Figure 44-6 Installation diagram of a room cooler showing the window-sealing strips and filler boards.

Figure 44-7 Installation diagram of a room cooler showing the sponge rubber seal between the top of the lower sash and the upper sash of a double window.

can be installed in any size unit. Power-receptacle configurations depend on the amperage drawn.

PTAC units are efficient, quiet, and easy to install. Temperature efficiency is usually stated in terms of EER. The EER is equal to the cooling output in BTU/hr divided by

Figure 44-8 Vertically constructed window unit for horizontal sliding window.

(a)

(b)

(c)

Figure 44-9 (a) Exterior view of a packaged terminal air conditioner (PTAC); (b) interior view; (c) console type unit.

the power input in watts under standard rating conditions. Standard rating conditions set up by AHRI are based on 80°F db, 67°F wb for the indoor entering air, and 95°F db for the outdoor ambient air. For example, a unit with an output of 6,600 BTU/hr and 660 W input, under standard conditions, would have an EER of 10 (6,600/660), which is considered a good rating.

44.7 PTAC COMPONENTS AND INSTALLATION

Figure 44-10 shows the location of the following essential parts: (1) indoor fan cover, (2) temperature control, (3) heat/cool/fan switch, (4) evaporator, (5) temperature sensor, (6) compressor, (7) condenser, (8) metering device, (9) condensate level float/drain, and (10) condensate pan. The air filter is located behind the front return-air panel and can be easily changed (Figure 44-11).

(a)

(b)

(c)

Figure 44-10 Expanded views of a PTAC unit listing major parts.

Figure 44-11 Air filters for PTAC.

SERVICE TIP

Most PTAC units use rotary compressors and capillary-tube metering devices. Rotary compressors have an excellent service life for this application, provided that the condenser is kept clean. A dirty condenser will raise the high-side pressure. High compression ratios will cause refrigerant to break down, and rotary compressors are unusually susceptible to damage from excessive heat because the motor is on the high side of the system. A dirty evaporator coil, as shown in Figure 44-12, should be cleaned and will also signal that the condenser needs to be checked. A small vacuum cleaner may be used for cleaning, but be very careful not to damage or bend any of the fins. These are very thin and are in place to increase surface area and heat transfer. If the condenser fins become bent, the air flow will be restricted, which will also create higher compressor discharge pressure.

44.8 PTAC CONTROLS

Most units are provided with the following choices (Figure 44-13):

OFF	turns unit off
FAN ONLY	indoor fan operates
COOL	provides cooling with indoor fan
HEAT	provides heating with indoor fan
HI	high fan speed
LOW	low fan speed

The following additional controls are provided:

- **Adjustable temperature limiting device** Limits the range of the room thermostat.

Figure 44-12 Dirty evaporator coil.

(a)

(b)

Figure 44-13 (a) Controls to operate unit; (b) DIP switches for controls.

- **Outside air damper** Control lever can be positioned to permit zero for fully open supply of outside air.
- **Fan cycle switch** Allows continuous or intermittent fan operation.
- **Remote thermostat (optional)** Unit can be wired to use a remote wall-mounted thermostat rather than the one normally supplied in the unit.
- **Front desk control interface (optional)** Units may be individually started and stopped with an energy-management panel from a central location.
- **Room freeze protection (optional)** Overrides OFF signal when room thermostat goes below 40°F.

44.9 STAND-ALONE AIR-CONDITIONING UNITS

A stand-alone air-conditioning unit for residential use requires an air handler outfitted with an evaporator coil, metering device, drain pan, transformer, blower assembly, and housing. The air handler is connected to its own duct system. There are three configurations of air handlers: vertical upflow, vertical downflow, and horizontal.

A vertical stand-alone is shown in Figure 44-14. The blower is drawing air across the refrigeration coil (Figure 44-15) and delivering it out through the top of the unit (Figure 44-16). The air passes across the coil, and refrigerant passes through the inside of the copper tubing (Figure 44-17). The refrigerant is supplied and returned from the coil through inlet and outlet distribution manifolds (Figure 44-18). The R-410A scroll compressor used for this unit is located below the blower and coil (Figure 44-19). The refrigerant lines pass upward through the air-handler casing to the refrigerant coil (Figure 44-20). A condensate drain line, often made up from PVC piping, will be connected to direct

Figure 44-14 Stand-alone AC unit.

Figure 44-17 Refrigerant flows through copper tubing.

Figure 44-15 Blower and refrigerant coil.

Figure 44-18 Refrigerant is distributed to and from the coil.

Figure 44-16 Blower discharge located at top of the unit.

water away from the drip pan located under the refrigerant coil (Figure 44-21).

The major disadvantages of a stand-alone air-conditioning unit are the type and location of the condenser. The stand-alone will be conveniently located inside the conditioned building. Therefore it is impractical to use an air-cooled condenser unless the heat can be rejected to the outdoors in some convenient fashion. Most stand-alone air-conditioning units will have a water-cooled condenser. This will require a continuous source of cooling water or some fashion of cooling water loop.

Figure 44-19 Compressor assembly.

Figure 44-20 Refrigerant lines leading from compressor up through cabinet to the coil.

44.10 RESIDENTIAL SPLIT SYSTEMS

For many air-conditioning systems, it is not practical to place all components in a single package, particularly those that involve the use of air-cooled condensers. The air-cooled condenser must have access to outside air, so it is best placed outside. For this reason, split systems have been developed with the inside unit consisting of a fan coil unit, with or without heating; an outside mounted air-

Figure 44-21 PVC pipe condensate drain line.

cooled condensing unit; and connecting refrigerant piping between the two, as shown in Figure 44-22.

TECH TIP

The final stage in manufacturing for split condensing systems is at the residence. Manufacturers have no control over the individuals who perform this last vital step in the production of their equipment. Manufacturers can't even insist that a matching system is installed. This final stage in manufacturing has a greater influence on the performance of a system than anything that the manufacturer can do. If the system is not installed with the correct size air duct systems, electrical wiring, and many other factors, the result can be the system providing poor performance or a reduction of its operational life. It is therefore very important that all of the manufacturer's specifications and guidelines be followed during installation so that your customer's system can be its most efficient and have the longest life possible.

Air-Cooled Condensing Unit

A typical split outdoor air-cooled condensing unit for residential settings is shown in Figure 44-23. This unit consists of a compressor, condenser coil, a condenser fan, and the necessary electrical control box assembly. On residential condensing units, a fully hermetic compressor is used.

The condenser coil is a fin-and-tube arrangement that varies in design from manufacturer to manufacturer. A large surface area is desirable, and many units offer almost a complete wraparound coil to gain maximum coil surface area. The coil tube depth is limited to reduce resistance to airflow.

Figure 44-22 Residential add-on cooling to furnace installation.

Figure 44-23 Outdoor condensing unit for residential split system.

TECH TIP

Condenser fan motors turn at slower speeds than indoor blower motors. Not all condenser fan motors spin at the same rpm. Some operate around 1,000 rpm, while others may operate around 800 rpm. It is important when changing out a condenser fan that one of the exact same rpm be used. The fan blades are designed to move air at a certain speed. If the fan blade is spinning faster than it was designed for, it will not operate as efficiently. Increasing the rpm does not mean that you are going to increase the airflow. In addition, the height that the fan extends into the fan shroud is important. If the fan blade is too low or too high, it will affect the airflow from the condenser. Mark the height of the blade before removing it to be sure it is put back in at the same height.

The condenser fan varies in design but is usually a propeller-type fan, which can move large volumes of air through clean coils, which in turn offer low resistance (Figure 44-24). Airflow direction is a function of the cabinet and coil arrangement, and there is no one best arrangement. Most units, however, use draw-through operation over the condenser coil (Figure 44-25). Outlet air can have an effect on surrounding plant life. Top discharge is the most common arrangement. Fan motors

Figure 44-24 View of the interior of the condenser with propeller-type fan blades.

Figure 44-25 Air is drawn through the condenser from the outside and discharged out through the top.

are sealed or covered with rain shields. Fan blades are shielded with a grille for the protection of hands and fingers (Figure 44-26).

SERVICE TIP

Axial fans, like those on condensers, are high volume and low static. If the coils on a condenser are dirty, the fan will simply churn the air and throw it off the fan blade tips. You can actually take a very dirty condenser and place a sheet of paper in the center of the fan and it will suck it down while throwing the air off the fan tips. A clean condenser has a column of air that rises straight up from the fan. By feeling how the air is flowing, a technician can determine to some extent whether the coil is clean or dirty. An easy example of this is to place a box fan flat on a table, point it up, and turn it on. You will feel the air on the fan coming out the side and little or no air movement in the center. As the fan is lifted off the table, the correct airflow will be established, and the air will no longer come out the side of the blades.

Figure 44-26 Grille-type fan guard.

Figure 44-27 Typical evaporator used on a split AC.

Evaporator Coils

A typical evaporator used on a split air-conditioning system is shown in Figure 44-27. Coil cases or cabinets are insulated to prevent sweating, and all have pans for collecting condensate water runoff. Plastic pipe may be used to connect condensate drain water to the nearest drain. If no nearby drain is available, a small condensate pump may be installed to pump the water to a drain or to an outdoor disposal arrangement.

44.11 HEAT PUMPS

Heat pumps are commonly used for split systems. This is because heat can either be rejected or absorbed by the outside unit. On hot days in the summer when air conditioning is required, the unit will operate like a normal split air-conditioning system. The outside unit will operate as a

Figure 44-28 Outside unit for air-to-air heat pump.

condenser rejecting heat, and the inside unit will operate as an evaporator to cool the inside air. On colder days in the winter, the system will reverse and the outside unit will absorb heat from the outside air. This heat is transferred to the indoor unit, which now operates as the condenser and heats the inside air. This type of air-to-air heat pump is very common in climates where the outside temperatures do not fall very far below freezing in the winter. When outside temperatures do fall below the normal operating range for the unit, an electrical resistance heater will turn on. The cost for supplementing with this type of electric heat, however, is often far more expensive as compared to operating the normal heat pump cycle. Even so, heat pumps are used in colder climates, but they are arranged differently. For further information, all types of heat pump applications are explained in Section 8, Heat Pump Systems.

An outdoor unit for an air-to-air heat pump is shown in Figure 44-28. It can operate as either a condenser or an evaporator. The indoor unit is suspended from the roof in the attic by chain hangers to save space (Figure 44-29). The indoor unit has a drain pan located underneath it to catch any condensate to prevent leaks coming through the ceiling below (Figure 44-30). This indoor unit also has a water loop that is augmented by solar heating panels located outside, on the roof of the building.

44.12 MINI-SPLITS

Mini-split systems are similar to conventional split systems except they are smaller. They are typically used to cool or heat one space and not the whole building. The major advantage is that air ducting is not necessary. In some ways these are similar to window air-conditioning units and PTACs, but they do not require a window and they are more versatile. For example, mini-split indoor units can be placed anywhere in the home and multiple indoor units can be connected to a single outdoor unit. Mini-splits are available for cooling only

or as heat pumps. This is possible because there is an outside unit and an inside unit (Figure 44-31). For installation, all that is required is a drilled hole through an outside wall for the piping and wiring connections.

44.13 AIR QUALITY

Air quality is sometimes neglected on air-conditioning systems, but an increasing emphasis is being placed on air quality both at home and the workplace. One simple task is to routinely change air filters (Figure 44-32). In some cases

(a)

(b)

(c)

Figure 44-32 (a) Grille-type air filter cover on stand-alone air-conditioning unit; (b) air filters; (c) air filters for mini-split.

(a)

(b)

Figure 44-33 (a) Radon-mitigation blower; (b) radon gas is discharged above the roof line.

this can be done by the homeowner, but the homeowner might not be able to acquire the right type and style of filter required for the unit. A routine system check, and filter replacement, can often save the customer time and money in the long run.

Radon

A dirty air filter can be obvious, but it's not always what you can see that is the most harmful. This is the case with radon gas, which seeps up from the ground and enters into buildings. This type of seepage is prevalent in areas of the country that have large underground granite formations. Concentrations of radon gas over time can lead to serious health consequences for the building's occupants. In these areas, local regulations protect homebuyers. If a home is tested and found to be above the normal acceptable limits, then a radon-mitigation system must be installed before the home can be sold. There are

Figure 44-34 Manometer located in basement for radon-mitigation system.

different methods to accomplish this. One of the most common is to drill holes into the concrete basement floor or slab. A continuously operating blower draws the air and gas out of the building and terminates above the roof line (Figure 44-33). A manometer located in the basement provides a quick visual check that the blower is operating properly (Figure 44-34).

UNIT 44—SUMMARY

In this unit you learned about different types of residential unitary air-conditioning systems, such as room air conditioners and split-system conditioners. Unitary equipment is factory built to be as complete as possible and fairly simple to install.

Room air conditioners are commonly found in many residential homes as well as small office buildings. They are relatively low in cost, easy to install, and can be used in almost any type of structure. A disadvantage of room air conditioners is that they may either block part of the window area and prevent the window from being opened or require a special hole through the wall. A common problem with window air-conditioning units is the nuisance trips of the residence circuit breakers.

Split systems have only the evaporator fan coil on the inside of the building. Split systems do not have the humming noise often associated with window units because the air-cooled condensing unit and compressor are mounted outdoors. However, these systems require considerably more fieldwork during installation because the refrigerant piping is assembled at the residence. It is very important that the system components be matched according to manufacturer specifications. Any change in design criteria in the field may adversely affect the system's performance.

WORK ORDERS

Service Ticket 4401

Customer Complaint: New Window Air-Conditioning Unit Keeps Tripping the Circuit Breaker

Equipment Type: 13,700 BTU Window Air Conditioner

After talking to the customer, the technician checks out the unit and finds nothing wrong. The unit is drawing 10 A and is on a 15-A breaker. There are numerous other household appliances on the same breaker. The technician checks the amperage draw at the breaker panel, and it measures 16.5 A. The technician recommends locating the unit to another room, where there is a lesser load on the wiring or to install a designated circuit for the new window AC unit. The customer is going to call an electrician to have a designated circuit installed.

Service Ticket 4402

Customer Complaint: Airflow Seems Low Since Adding Air Conditioning to the Existing Furnace

Equipment Type: 3-Ton 14-SEER Split System

The technician arrives at the job site, and after discussing the problem with the homeowner decides to check the indoor airflow. The technician discovers that there is not enough airflow for 3 tons of air conditioning. The furnace has a variable speed motor. The technician increases the motor speed to move more air. The technician rechecks the airflow and determines that the installers did not check to ensure there was sufficient airflow after installing the new coil. The airflow is now within industry standards, and the homeowner is satisfied.

Service Ticket 4403

Customer Complaint: Fan on Outside Unit Is Not Running

Equipment Type: 4-Ton 10-SEER Split System

The technician talks to the customer and then proceeds to analyze the system. The technician discovers that the

fan motor is bad. The technician removes the fan motor and discovers the rated rpm is 875. The only motor on the service truck is rated for 1,050 rpm. Since the new motor must be within manufacturer's specifications, the technician goes to the supply house and buys a motor rated for 875 rpm. After installing the proper motor, the technician analyzes the system and determines that it is operating within the manufacturer's specifications.

UNIT 44—REVIEW QUESTIONS

1. List the primary advantages of a room air conditioner.
2. List the disadvantages of a room air conditioner.
3. What is a common problem with window air-conditioning units?
4. What are the two parts of a window air-conditioning unit?
5. How is the energy efficiency ratio (EER) calculated?
6. What is the primary difference between the EER and the SEER?
7. What is an advantage of a propeller-type fan?
8. Most PTAC units use what type of compressors and metering devices?
9. Why are there thin metal fins located on the tubes of evaporators and condensers on PTAC units?
10. What can happen if you tip the old window air-conditioning unit as you move it?
11. What are the three basic configurations of stand-alone air-conditioning air handlers?
12. What are the major disadvantages of a stand-alone air-conditioning unit?
13. Why are heat pumps often used on split systems?
14. What are some advantages of mini-split systems?
15. What is the concern about radon gas?
16. Explain why split systems were developed.
17. Why is a quality installation one of the most important phases of the manufacturing process?
18. Name the four major components of a condensing unit.
19. Describe why it is important to replace a fan motor with one of the exact same rpm.
20. In a condenser coil, why is the coil tube depth limited?

UNIT 45

Residential Split-System Air-Conditioning Installations

OBJECTIVES

After completing this unit, you will be able to:

1. list the various installation components of a residential split-system air conditioner.
2. explain the installation process of the outdoor condensing unit.
3. explain the installation process of the indoor evaporator and/or air handler.
4. explain the methods used to select and install the refrigerant line sets.
5. explain the electric wiring requirements of the system.
6. explain the various methods used to check the airflow across an evaporator.
7. explain the various methods used to check the refrigerant charge of the system.

45.1 INTRODUCTION

A popular style of air-conditioning system used in many homes is the split-system air conditioner. A typical split system consists of as few as two sections. There is an outdoor condensing unit and an indoor evaporator coil and air handler or an indoor evaporator coil and furnace. Many times these systems are connected to an existing forced-air furnace, but they can also be installed as a stand-alone system.

These systems must be assembled at the customer's home by a qualified technician. The installing technician must be proficient in the basic techniques used to run refrigerant lines, drain lines, and electric wiring. The technician must also possess the skills required to connect the system to the new or existing duct system.

45.2 PLANNING THE INSTALLATION

The success of any installation lies in its planning. Any equipment selection should be properly sized using the guidelines for load calculation as set forth in the Air Conditioning Contractors of America's (ACCA) Manual J. Proper planning allows for efficient and trouble-free installation. Without proper planning, costly mistakes can and probably will occur, increasing the costs for the installing contractor.

Part of the planning procedure requires a technician to reference the manufacturer's installation manual and determine the installation requirements of the system. This will allow the technician to determine the refrigerant line sizes to run, the electrical requirements of the system, and any other manufacturer's recommendations required to properly install the system. The installing contractor should also review the local code requirements and make sure any code-related issues are covered.

A technician should also develop a list of materials needed for the installation. This will ensure that all the correct materials arrive on the job. Leaving an installation to get more materials or the correct material will cost valuable time on the job.

Proper planning also allows a technician to choose the proper location of the equipment. This is especially important when deciding where to install the outdoor condensing unit. A technician should always discuss and get customer approval on the placement of the outdoor condensing unit. Installing it in the wrong location will cause problems for the contractor and the customer.

A technician should also develop a sequence for the installation to allow a more efficient installation process. A typical installation sequence is as follows:

- Determine the required BTU capacity of the system to be installed.
- Select the equipment and system components for the installation.
- If needed, configure the indoor section for an upflow, downflow, or horizontal installation.
- Set indoor coil in place.
- Install any needed ductwork.
- Set the outdoor pad in place, and level.
- Set condensing unit in place.
- Install refrigerant lines.
- Leak test and evacuate/dehydrate refrigerant lines.
- Run the required electrical wiring and connect up to the equipment.
- Install condensate drain line and pump (if needed).
- Weigh in the correct amount of refrigerant according to the manufacturer's specifications.
- Start up system, confirm airflow, and check/adjust refrigerant charge.
- Clean up work area.
- Explain operation, warranty, and any required maintenance of the unit to the customer.

Equipment Sizing

Part of the installation process is choosing the right system components. The installing contractor must first determine the proper capacity of the equipment needed to satisfy the cooling and heating requirements of the structure. To determine the capacity needed, a heat-gain calculation must be completed for the structure. For residential structures, the ACCA's Manual J is the industry standard. There are also many software programs available that will allow a contractor to perform this calculation.

It is important for a contractor to choose the right size system. Oversizing or undersizing a system can create problems for the contractor and the customer. An oversized system will not run long enough to properly dehumidify a structure. An undersized system will not be able to handle the load when the outdoor temperature is high.

Equipment Selection

Once the BTU requirements of a structure have been determined, the proper system components can then be selected. The outdoor condensing unit, such as the one shown in Figure 45-1, will be selected based on its BTU capacity for both sensible and latent cooling loads as outlined in ACCA Manual S, its seasonal energy efficiency ratio (SEER), and the type of condenser and voltage requirements. For residential systems, a 208/230 single-phase voltage, air-cooled condenser is the standard and is used on most installations. The BTU capacity of the outdoor condensing unit will be chosen to match the BTU requirements of the structure. The SEER rating will be chosen based on the customer's requirements. The SEER is the operating efficiency rating of the condensing unit. The higher the SEER rating, the more efficient the condensing unit will operate. The installing contractor will normally offer their customer the option of choosing the SEER rating. Currently the minimum SEER rating available for new systems is 13.

There are two types of installations for the indoor section of the system. One type is where the air-conditioning system is connected to an existing forced-air furnace. In this type of installation, an evaporator coil and drain pan are

Figure 45-1 A typical outdoor condensing unit.

attached to the existing furnace, and the air-conditioning system will use the same blower assembly and duct system as the forced-air furnace. There are three different styles of evaporator coil and drain pan assemblies that can be used. One style is a cased-coil assembly, which consists of an evaporator coil, metering device, drain pan, and housing. The complete assembly is designed to fit directly on top of a forced-air furnace, and the system's plenum (duct section) is connected to the top of this assembly. An uncased coil can also be used. This assembly consists of just an evaporator coil, metering device, and drain pan. It does not have its own housing. The assembly is designed to fit directly in the plenum of the duct system. The third option is a half-cased coil, which is an evaporator coil, metering device, and drain pan contained in a housing covering only half of the coil.

The other type of indoor installation is where the air conditioner is a stand-alone system (Figure 45-2). An air handler is used for this type of installation, consisting of an evaporator coil, metering device, drain pan, transformer, blower assembly, and housing. The air handler is connected to its own duct system. There are three configurations of air handlers: vertical upflow, vertical downflow, and horizontal.

The BTU capacity of the evaporator coil assembly or air handler selected may be different from the capacity of the outdoor condensing unit. Many applications require a larger evaporator to obtain a particular SEER rating or sensible heat ratio.

The metering device used for a particular installation may also need to be selected. The indoor unit may come with a factory-installed metering device; however, it may

Figure 45-2 A stand-alone air-conditioning system. (Courtesy of Goodman Manufacturing Company)

Figure 45-3 A fixed orifice used on a residential air-conditioning system.

need to be changed out if it does not match the requirements of the system. Some manufacturers ship coils today with no metering device installed, allowing the installer to use the one that matches both the unit capacity needs and the refrigerant type being used, such as R-22 or R-410A. The metering device must match the BTU capacity of the condensing unit and indoor evaporator. There are two general types of metering devices used: the fixed orifice (Figure 45-3), and the thermostatic expansion valve (TEV) (Figure 45-4).

Other Installation Components

There are several other installation components that must be chosen to complete an installation. The outdoor condensing unit will need an electrical disconnect switch (Figure 45-5). There are two types of disconnect boxes. One type contains only a switch, and it may or may not have a fuse. The other type uses a circuit breaker for both the switch and electrical overcurrent protection. An outdoor-rated watertight flexible electrical cable, generally referred to as a whip (Figure 45-6), connects the system's disconnect to the condensing unit.

An outdoor pad must also be selected to set the condensing unit. This pad can either be a poured concrete slab or a prefabricated reinforced plastic pad (Figure 45-7). Most

Figure 45-5 A disconnect switch for an outdoor condensing unit.

Figure 45-6 A whip used on an outdoor condensing unit.

Figure 45-4 A TEV used on a residential air-conditioning system.

Figure 45-7 Prefabricated reinforced plastic pad. (Courtesy of DiversiTech Corp.)

Figure 45-8 ACR tubing used for air-conditioning and refrigeration systems.

equipment manufacturers recommend that the equipment pad be 2 to 3 in larger on all sides than the condenser to reduce dirt spattering into the coils.

Appropriately sized refrigerant lines will also need to be selected. Copper air-conditioning and refrigeration (ACR) tubing is used. ACR tubing is processed for use on air-conditioning and refrigeration systems. Its interior is processed to be clean and dehydrated and will not add any contaminants to a system. It is sized by its outside dimensions, which differs from pipe used in the plumbing industry. Copper pipe used in the plumbing industry is sized by its inside diameter.

Type L soft ACR tubing is sometimes used (Figure 45-8), and hard-drawn ACR can also be used. Soft ACR tubing can be purchased in rolls of 50-ft lengths and cut to size on the job. Hard-drawn ACR tubing can be purchased in 20-ft lengths and can also be cut to size on the job. To prevent condensation from forming on the suction line, it is typically insulated with closed cell foam (Armaflex® is often used). This insulation is sized based on the outside dimension tubing size and the wall thickness required. Insulation is available with wall thicknesses of $\frac{3}{8}$ in, $\frac{1}{2}$ in, $\frac{3}{4}$ in, and 1 in. Insulation with a $\frac{3}{8}$ -in wall thickness is normally used on residential split-system installations.

Wholesalers also sell ready-made line sets, consisting of an insulated suction line and a liquid line in various tubing diameters and lengths. These line sets are available in lengths of 15 ft, 25 ft, 35 ft, and 50 ft with tubing diameters of $\frac{5}{8}$ in to $1\frac{1}{8}$ in for the insulated suction lines and $\frac{3}{8}$ in to $\frac{1}{2}$ in for the liquid lines.

A thermostat (Figure 45-9) will also need to be selected. There are many different styles of thermostats. Thermostats are available as programmable and nonprogrammable as well as digital and mechanical. Different thermostats will have different features and capabilities depending on the system design. A contractor should consult with the customer as to the type of thermostat they prefer. A contractor will also need to select the wiring for the thermostat. Thermostat wiring is available in various gauge sizes and with different numbers of conductors. Residential installations will generally use a minimum of 18-gauge wire with either two, five, or eight conductors depending on the sys-

Figure 45-9 An air-conditioning thermostat.

Figure 45-10 A condensate pump used when no drain is close to the air conditioner's evaporator. (Courtesy of DiversiTech Corp.)

tem and components to be installed. Some multistage heat pump applications may require as many as twelve wires.

Condensate tubing and fittings will also need to be selected. Normally, the condensate drain lines used will be $\frac{3}{4}$ in Schedule 40 PVC. Be sure to check the local codes, as some may require $1\frac{1}{4}$ -in drain lines after condensate leaves the unit. If there is not a convenient open drain close to the indoor assembly, a condensate pump (Figure 45-10) will also need to be selected to pump the condensate to an appropriate drain. The material used, as well as the location into which the condensate is drained, may be subject to local code.

45.3 INSTALLING THE INDOOR EQUIPMENT

Normally, the first part of the installation process is the installation of the indoor equipment. Depending on the type installed, the process will be slightly different. A cased coil, an uncased coil, and an air handler will all require different installation procedures.

Figure 45-11 An uncased evaporator coil.

Installing Cased Coils

When a cased coil is used on an installation it will generally sit on top of a forced-air furnace or below the furnace on a downflow system. If the coil is used on an existing system, the supply-air plenum will first need to be removed. Sometimes this also requires removing some other system components, such as the furnace's vent piping.

Once the supply-air plenum is removed, the new cased coil is set on top of the furnace and is leveled to ensure proper drainage of the condensate. A new supply air plenum is then fabricated and reinstalled between the top of the cased coil and the existing ductwork. All connections must be properly sealed to prevent air loss.

Installing an Uncased Coil

When an uncased coil (Figure 45-11) is used on an installation, it will generally be installed inside the supply-air plenum. One side of the supply-air plenum will need to be removed or cut to allow the uncased coil to be slipped into the plenum.

To install the coil, first shut off power to the furnace and remove any system components in front of the side of the plenum on which the coil is to be installed. Next, lay out a pattern on the supply-air plenum for the coil access opening and cut the opening. The access opening should allow the coil to sit close to the furnace but should be at least 4 in above the furnace's heat exchanger. Once an opening is created, install a set of brackets to hold the coil assembly, making sure the brackets installed are level to allow for proper drainage of the coil's condensate. Next, insert the coil into the plenum and place on the installed brackets. More than likely there will be open spacing between the coil and the inside walls of the plenum. These openings must be covered to prevent the supply air from bypassing the evaporator coil. Normally, a piece of sheet metal is installed between the coil and the inside walls of the plenum to cover this opening. Once the coil is set in place and leveled, a sheet metal patch will need to be fabricated to cover the opening on the side of the plenum. All joints must be sealed to prevent air leakage.

SERVICE TIP

Manufacturers provide extensive testing with their condensers and evaporator coils. Some manufacturers may have many different air-handler/evaporator-coil combinations for a single condenser. This research is carried out in scientific laboratories so that the most ideal combinations can be determined. Often, however, in the field, technicians simply purchase from a supply house a coil that is most convenient and not one specifically designed for the condenser. Any change in design criteria done in the field will adversely affect performance, not enhance performance. Manufacturers are under tremendous pressure from regulatory agencies to produce the highest possible system efficiency. If a change in coil size could enhance efficiency, it would have been done in the lab and there would be test criteria and procedures set up. It is not recommended in any way that technicians undertake design changes from the manufacturer's recommendations. These matched systems are available from the manufacturer and are available from the AHRI through publications and on their Web site.

Add-on Coils

Using a split system offers the opportunity to add cooling to an existing residential system heating unit where the necessary modifications are feasible. Add-on coils are available in a number of configurations to fit various types of heating units (Figure 45-12). This figure also shows the manner in which the position of the coils is related to the air-handling unit. Coils are supplied for upflow, horizontal, and downflow furnace applications.

SAFETY TIP

Codes prohibit the installation of an evaporator coil before a gas or oil furnace heat exchanger. If the coil is placed before the heat exchanger, then condensate will form in the heat exchanger, causing it to rust out quickly.

Figure 45-12 An uncased evaporator coil.

Figure 45-13 A single-circuit add-on split-system installation.

An important consideration in applying an add-on cooling coil to an existing furnace is the air resistance it adds to the furnace blower. During the heating cycle, the coil is inactive and dry. In summer, when the unit is cooling and dehumidifying, the coil is wet. The wet coil will add an average of 0.20 to 0.30 in of water column static pressure loss. This added resistance may require a change in furnace blower speed and an increase in motor horsepower. If the installation is a new system, a furnace blower should be selected that is capable of producing sufficient external static pressure to deliver the required amount of air. Wiring and piping a typical single-circuit add-on split system is shown in Figure 45-13.

Installing an Air Handler

Air handlers will often come as an assembly with a blower and refrigerant coil (Figure 45-14a). Since an air handler is a complete assembly, its installation consists of setting the air handler in place and connecting the ductwork, refrigeration lines, and condensate lines (Figure 45-14b). A supply plenum will be connected to the discharge of the air handler and a return boot connected to its inlet.

Most air handlers can be installed in the vertical upflow, the downflow, or the horizontal position. Normally the air handler will come ready for an upflow installation. If used in the downflow or horizontal position, some modifications will need to be made to the unit. Consult the installation manual to determine these modifications.

45.4 OUTDOOR CONDENSING UNIT INSTALLATION

The location of an outdoor condensing unit is an important part of the overall installation. An incorrectly placed condensing unit can cause problems for both the installing

(a)

(b)

Figure 45-14 (a) Air handler with blower and refrigeration coil; (b) condensate drain for air handler.

Figure 45-15 A typical placement of an outdoor condensing unit.

contractor and the customer. The installer should always discuss the location of the condensing unit with the customer and verify the location chosen is not objectionable. Figure 45-15 shows the placement of an outdoor condensing unit. The following is a list of recommendations when deciding on the location of the outdoor condensing unit:

- Do not install a unit where the operating noise will be objectionable to the customer or their neighbors.
- Avoid locating the unit in direct sunlight.
- Do not locate where water, snow, or ice from the roof or eaves can fall directly onto the unit or where the roof overhang can cause recirculation of the air exhausted from the unit.
- Do not locate under decks or porches unless the clearance dimensions specified by the manufacturer are met.
- Locate the unit close to the building to minimize line length and to avoid installing underground piping.
- Locate the unit so that it can be readily serviced.
- Maintain required clearances around the unit for proper airflow.

Once the location has been chosen, the pad for the condensing unit can be set in place and leveled. The condensing unit can then be set in place on the pad. The condensing unit can be mounted and secured directly to the pad using a construction adhesive or tie-down bolts (some local codes may require this). If construction adhesive is used, make sure not to block the drain holes located on the bottom of the condensing unit.

SAFETY TIP

Improperly lifting heavy objects can cause serious injury. A technician should always lift with the legs rather than the back; the leg muscles are much stronger than the back muscles. For added protection, wear a back support. Follow these recommended steps when lifting heavy objects:

- Move close to the object to be lifted.
- Squat down. Keep your back straight and your chin tucked in. Position one foot behind the other, with the forward foot at the side of the object.
- Grip the object from underneath and wrap your hands around the object.
- Draw the object close to your body.
- Lift by slowly straightening your legs. Try to keep the weight centered over your legs as much as possible.

TECH TIP

Noise is recognized as an environmental pollutant. Outdoor air-cooled condensing units are sound-producing mechanical devices, which some cities and towns regulate. Early attempts to create local ordinances prompted action on the part of the ARI in 1971 to establish a sound rating standard that local communities could adopt.

AHRI Standard 270 applies to the outdoor sections of factory-made air-conditioning and heat pump equipment (unitary air conditioners). Under the program, all participating manufacturers are required to rate the sound power levels of their equipment in accordance with the technical specifications contained in this standard. Test results are submitted by the manufacturers to AHRI for review and evaluation. Units are sound rated with a single number: the sound rated number (SRN). Typical ratings are between 14 and 24.

45.5 INSTALLING THE REFRIGERANT LINES

To connect the indoor coil to the outdoor condensing unit, ACR tubing will need to be run and connected to each of these devices. One pipe run will be the vapor suction line and the other the liquid line of the system. These lines must be properly sized and installed to ensure that the system operates in accordance with the manufacturer's specifications. Incorrectly sized or installed refrigerant lines can cause the system to operate outside its rated capacity or cause damage to the system's compressor.

Before installing the refrigerant lines, make sure the metering device installed in the indoor unit is correctly sized for the application. If a fixed-orifice metering device is used, verify that it matches the rating for the outdoor condensing unit. Some new condensing units will come shipped with an appropriately sized fixed orifice, as shown in Figure 45-16. If the indoor unit's fixed orifice does not match the one that came

Figure 45-16 A fixed orifice shipped with a new condensing unit.

with the condensing unit, it should be replaced with the one supplied by the condensing unit manufacturer. Many coils now ship with no metering device, as one is added based upon capacity requirements and refrigerant type.

The overall length of the refrigerant line should be kept as short as possible. Do not exceed the maximum length as stated by the manufacturer. Generally pipe runs can be up to 175 ft. If a line set exceeds a distance specified by the manufacturer, special modifications will need to be done to the system. Most manufacturers will have an installation bulletin detailing their requirements for these long line applications.

The diameter of the refrigerant lines run must be properly sized; it is based on BTU capacity and the length of the refrigerant lines used on the system. Always follow the recommendations of the equipment manufacturer; the required line sizes will normally be given in the installation manual shipped with the equipment. When the condensing unit is installed above the evaporator unit, suction line size (if oversized) can affect the velocity of the refrigerant and the refrigerant's ability to carry oil.

TECH TIP

Do not base the line sizes on the stub connections at either the condensing unit or the indoor coil. These stub connections are based on an average installation and do not apply to every installation.

Suction lines should always be insulated to prevent water damage from condensation and to limit the refrigerant from becoming excessively superheated on the way back to the compressor. Liquid lines are normally not insulated

Figure 45-17 Soft ACR tubing is easier to bend and form.

except if there is a possibility that the liquid will gain excessive heat on its way to the metering device, such as if it is run through a hot attic.

Either soft or hard-drawn ACR tubing can be used. Soft tubing is normally used, as it is easier to bend and form (Figure 45-17), making the installation of the tubing easier for the technician. When bending this tubing, use a tube bender to prevent kinking. When elbows are required, use a long-radius elbow instead of short. Long-radius elbows offer less resistance to flow.

Many times the ACR tubing used will need to be cut to length. Make sure to use the appropriate tubing cutters (Figure 45-18); they allow for a clean and square cut. Avoid using a hacksaw, as it leaves too many burrs on the tube ends as well as filings that can contaminate the system. Always deburr the tubing ends after cutting them. Do not allow any of the burrs to fall into the copper tubing.

Figure 45-18 Use a tube cutter for a clean and square cut.

Figure 45-19 The isolation valves on an outdoor condensing unit.

Instead of using fittings to join sections of tubing, many technicians will use a swaging tool to increase the diameter of one tube end, allowing the opposite end to be inserted into the enlarged end. This method allows for less soldered or brazed joints, leading to less chance of refrigerant leaks.

The tubing connections are joined using the brazing process. Always flow an inert gas, such as nitrogen, through the lines when brazing. This prevents the copper from oxidizing due to the heat. Oxidation will tend to flake off during operation, which will plug up filter driers and metering devices.

The condensing unit will normally contain two isolation valves (Figure 45-19), each with a stub connection. One of these stub connections is for the suction line and the other is for the liquid-line connection. Each of these isolation valves will also have a Schrader port to allow a technician to attach the refrigeration manifolds. On new systems these isolation valves are initially front-seated to hold a refrigerant charge contained in the condensing unit. When brazing the tubing to these stub connections, the core inside the Schrader must be removed. The valve contains a rubber packing that if overheated will be damaged. A core remover can be used to remove this Schrader core. A wet rag or a heat-sink material must always be wrapped around the valves to prevent them from being overheated during brazing (Figure 45-20).

Figure 45-20 Wet rag wrapped around valves during brazing.

When running the refrigerant lines, there should be support lines every 6 to 10 ft and within 2 ft of any bends. Insulated supports should be used to avoid any noise transmission and to avoid having the tubing come in direct contact with any water pipes or ductwork.

Normally, the refrigerant lines will need to run through some type of wall structure. When cutting through any wall, always check and recheck before cutting access holes—mistakes can be costly. When running refrigerant lines through a masonry wall, the pipe must be sleeved with a section of PVC tubing to prevent the deterioration of the copper tubing. This reduces the chance of a leak developing over time from the tubing rubbing on the masonry due to vibration. Always seal pipe penetrations with an appropriate sealant.

A liquid-line filter drier should always be a component included in the system. The best location for the filter drier is indoors as close as possible to the metering device, although most installations have them outside near the condensing unit. The desiccant contained in the drier will normally hold more moisture in a cooler environment. Some manufacturers install a liquid-line drier at the factory. If this is the case, be sure not to add another one, as this would result in two driers in series, which could cause a restriction.

Leak Testing

Once all the refrigerant lines are run and connected, the system needs to be leak checked. The lines and coil should be leak tested with dry nitrogen. Nitrogen makes a good initial leak-test gas because it is inexpensive and legal to release to the air. Pressurize the lines and coil to between 100 psig and the system's low-side test pressure. Never pressurize a system more than 150 psi. Make a note of the time and pressure. Use soap bubbles or an ultrasonic leak detector to check the line connections at both the inside and outside units. Also check any other mechanical or brazed joints in between. Finally, if the unit uses a field-installed expansion valve, check all connections on the expansion valve. After making all these checks, recheck the pressure. The system has passed the initial leak test if the pressure is the same as when the system was first pressurized.

An alternative method for leak checking a system is to pressurize the system with a small amount of HCFC-22 and nitrogen. Add enough refrigerant to pressurize the system to 2 to 3 psig with the HCFC-22 and then add a nitrogen charge on top of the refrigerant. Pressurize the system again to a test pressure as recommended by the equipment manufacturer. Once the system is pressurized, an electronic leak detector can be used to locate the refrigerant leak. Only use this mixture with R-22 systems. Never mix R-22 with R-410A.

TECH TIP

Vacuum pumps are used in conjunction with a quality vacuum gauge to properly evacuate a refrigeration system before refrigerant is added to an empty system. Before opening a vacuum pump and gauge to a system, it is a good practice to perform a blank-off test. A blank-off test is when a vacuum pump only pulls a vacuum on the vacuum gauge and manifold.

Performing a blank-off test before opening a vacuum pump and gauge to a system will allow a technician to verify that the vacuum pump and gauge are operating normally. It is better to identify a problem with either a vacuum pump or gauge before running on a system. Running a defective vacuum pump on a system is a waste of time; a sufficient vacuum level will not be obtained. Using a defective vacuum gauge will not allow a technician to determine if the appropriate micron level for complete evacuation is reached.

To perform a blank-off test, turn off the valve between the system and the vacuum gauge, manifold, and vacuum pump. Then run the vacuum pump until a 500 micron level is achieved. If a 500 micron level is achieved, the technician can safely assume that the vacuum pump and vacuum gauge are operating normally.

System Evacuation

Once the system is leak tested and is determined to be leak free, it needs to be evacuated. Release the nitrogen to the air and connect a vacuum pump and micron vacuum gauge. The system should be evacuated to a 500 micron level or the level recommended by the equipment manufacturer. Do not rely on a compound gauge, as they are not designed for deep vacuum detection.

Once a 500 micron level is achieved, shut off the pump and watch the micron gauge. A rise of 100 to 200 microns is normal. If the micron level rises above this but then levels out, try running the vacuum pump again, because there may be some moisture left in the system. If the micron level rises and continues to rise, there is probably a leak in the system, which must be repaired. Once the line set and evaporator have been properly evacuated, the isolation valves on the condensing unit will need to be opened to allow the refrigerant to flow into the rest of the system if the new condensing unit has a precharge of refrigerant. Remove the valve stem caps from the isolation valves and turn the valve stem fully counterclockwise to open the valves.

If the new condensing unit does not have a precharge of refrigerant, weigh in the correct amount of refrigerant based on the system match and length of line set. Follow the manufacturer's recommendations, which is always the best way to charge a system.

45.6 FIELD WIRING

The installation of a residential split-system air conditioner requires the installation of two dedicated line-voltage and two low-voltage electrical circuits. One dedicated line-voltage circuit services the outdoor condensing unit through an (if required, fused) outside disconnect switch. The line-voltage service to the outdoor condensing unit is normally a 208/240 V single-phase service rated at a specific amperage. The amperage rating needed will depend upon the size of the condensing unit installed. A separate low-voltage circuit is also required from the furnace or air handler to the outdoor condensing unit. This is

typically an 18-gauge two-conductor service used for the control circuit of the system of a cooling-only, single-stage system. The other dedicated line-voltage circuit is to the furnace or air handler. This is normally a 115 V or 230 V, 15 A or 20 A circuit. The second low-voltage circuit is for the system's thermostat connection. It is run from the furnace or air handler to the thermostat. Normally an 18-gauge, four-wire conductor is used. Some installations will require a five-conductor service if a 24 V digital thermostat is used. Newer multistage residential systems, which can have indoor air quality (IAQ) options, may require more wires. When connecting the low-voltage wiring of the system, always refer to the manufacturer's wiring diagram for the proper connections.

Choosing an Overcurrent Protective Device

When installing residential air-conditioning systems, the installing contractor must be sure that the appropriate type of overcurrent protection device is used with the outdoor condensing unit. There are three main types of overcurrent protection devices:

- Fuse
- Standard circuit breaker
- HACR circuit breaker

The type of overcurrent device to use will normally be stated in the installation instructions or on the rating plate of the condensing unit (Figure 45-21). Some manufacturers will use the following wording on the data plate to state the type of overcurrent device to use:

- If the rating plate states MAX FUSE _____ AMPS, then a fuse with the proper rating must be placed in the circuit. Normally, a fused disconnect will satisfy this requirement.
- If the rating plate states MAX FUSE or HACR CIRCUIT BREAKER _____ AMPS, then an HACR circuit breaker or fuse with the proper rating can be used.

Figure 45-21 A rating plate of an outdoor condensing unit.

- If the rating plate states MAX FUSE, HACR CIRCUIT BREAKER OR CIRCUIT BREAKER _____ AMPS or MAXIMUM OVERCURRENT PROTECTION DEVICE, then a fuse, HACR circuit breaker, or standard circuit breaker can be used.

The gauge of the electrical wire used also needs to be selected. The proper gauge must be selected to allow for the proper amperage draw without the possibility of overheating the wire. When wiring equipment, always use the type and gauge of wire recommended by the equipment manufacturer and only make adjustments based on local or national codes. The value marked MINIMUM CIRCUIT AMPS is used to determine the proper wiring size to use. The wire size rating is based on a maximum ambient temperature of 86°F. If this is exceeded, the wire size must be rechecked after being derated for its new value.

TECH TIP

Only use fuses or circuit breakers that are HACR rated. This type may be referred to as “slow-blow.” These fuses and breakers can handle the momentary high current draw that occurs during compressor starting without blowing or tripping. The technician must be familiar with the appropriate National Electrical Codes, Local Codes and the Manufacturer Instructions.

45.7 INSTALLING THERMOSTATS

The placement of the thermostat is also important for the overall operation of the system. An incorrectly placed thermostat could cause the structure to be too cold or too warm. Following is a listing of some general requirements when mounting a thermostat:

- It should be installed on an inside wall and not on an outside wall or a wall exposed to any unconditioned space.
- It should be mounted 52–60 in above the floor in an area with good air circulation.
- It should be mounted level.
- It should not be located in dead-air spots.
- It should not be located near diffusers.
- It should not be located near any radiant heat sources, such as direct sunlight or in close proximity to floor and table lamps.
- It should not be located near any concealed pipes or ducts.
- It should not be mounted on a wall that separates conditioned and unconditioned space.

Normally, 18-gauge wire is run from the thermostat to the indoor coil assembly. If the thermostat is located over 100 ft from the cooling equipment, 16-gauge wire should be used. Remember, the smaller the number, the larger the wire size.

Wiring is normally color coded to simplify the connections between the thermostat and heating/cooling equip-

ment. A typical color coding is shown below. Always check the manufacturer's instructions for the color coding of the low-voltage system, as not all manufacturers use this color coding.

- R Red: transformer power (24 V)
- G Green: fan control (the National Electrical Code allows the use of green as a current-carrying wire only on voltages less than 50 V)
- Y Yellow: compressor control
- W White: heating control

45.8 INSTALLING THE CONDENSATE DRAIN PIPING

Since the evaporator will often operate at a temperature below the dew-point temperature of the air drawn across it, water will be condensed from the air. The evaporator will have a drain pan located under its coil to collect this water. The water collected will need to be safely drained away from the evaporator. The installing technician needs to run a drain line from this pan to an open or vented drain. Laundry sink or basement floor drains are commonly used. Normally, ¾-in schedule 40 PVC is used as the drain line. However, other types of plastic pipe can be used, such as CPVC (chlorinated polyvinyl chloride), PP (polypropylene), and ABS (acrylonitrile-butadiene styrene).

The drain pan on the evaporator will normally have both a primary and secondary drain. Pipe connections are normally ¾-in FPT (female pipe thread) connection. The primary drain is the lower of the two, and a trap should be installed as close to the unit as possible if this location is under a negative pressure. The secondary drain is the upper connection and will allow water to drain from it, if the primary drain becomes clogged. Some applications do not require the use of a secondary drain; if it is unused it should be capped. These drain lines should be slightly pitched in the direction of flow and supported every 10 ft. A clean-out should be provided (Figure 45-22) to allow service and maintenance technicians to clean the drain line as needed.

The secondary drain connection serves a great purpose if the evaporator is installed in an area where water overflow can cause severe damage to a customer's property. If the primary drain becomes clogged, water will safely drain down through the secondary drain line. When used, the secondary drain should not be connected to the primary drain and should not be trapped. It should be piped to a location that is separate from the primary drain and visible to the owner. The line should be tagged to notify the customer to call for service if water is seen draining from this pipe.

For attic or ceiling installations, it is advisable to install a drain pan under the fan coil to also prevent water damage caused by an overflowing condensate line. If a drain pan is installed under the fan coil, the secondary drain from the evaporator pan can be directed to this pan. This pan must then be piped to a location that is both visible to the owner and will not cause any damage to the property. This line should then be tagged to notify the customer to call for service if water is seen draining from this pipe. Some units installed above finished ceilings have a safety switch located in the pan for shutdown in the event that the pan is

Figure 45-22 A clean-out for the primary drain line.

not draining properly. This limits expensive repairs due to water damage.

To cut and join PVC pipe as well as ABS and CPVC, the following procedure can be used:

- Use a plastic tubing cutter or a special cutter called a plastic tubing shear to cut the pipe. Avoid using a saw to cut this pipe. It will leave particles that could enter the pipe and cause a future clog.
- Deburr the pipe ends with a knife or file.
- Using an approved cleaning solvent, thoroughly clean the pipe ends and the inside of the fitting sockets.
- Apply a thin coat of primer to the tube end and the inside of the fitting sockets.
- Apply a thin coat of cement to the tube end and the inside of the fitting sockets.
- Immediately after applying the cement, push the pipe completely into the fitting sockets using a quarter-turn twisting motion until the pipe bottoms into the socket.

45.9 START-UP AND SYSTEM CHECKOUT

Once all of the system components have been installed, the system needs to be started up and checked out per the instructions supplied in the installation manual. If the compressor has a crankcase heater, many manufacturers recommend that the heater be energized for a minimum of 24 hours before starting the system. This prevents liquid refrigerant from being in the compressor on startup.

The system's fan should be energized and the airflow across the evaporator should be measured. There should be approximately 400 CFM (cubic feet per minute) per ton of airflow across the evaporator. For example, a 3-ton

residential air-conditioning system should have approximately 1,200 CFM of air flowing across its evaporator coil. However, airflow can be as low as 350 CFM per ton or as high as 450 CFM per ton to allow for changes to the sensible heat ratio to match specific requirements. If the airflow is too low, increase the fan motor speed per the manufacturer's instructions. If the airflow is too high, decrease the airflow per the manufacturer's instructions.

TECH TIP

There is a great deal of information available to technicians on the manufacturer's technical data sheets. All of this information is important, and if you learn how to properly use it you will become more valuable to your company and your customers. Most manufacturers provide explanations as to what each column of data can be used for. If you have difficulty understanding any of the material, most manufacturers or their distributors will provide you with an in-depth explanation of the data and how they can be used. Also consult ACCA Manual S for detailed instruction regarding equipment selection.

Checking and Adjusting the Airflow

If too little or too much air is delivered across the evaporator coil, the system will not function properly. *Too much* air moving across an evaporator coil will result in poor humidity control. *Too little* airflow will result in an iced evaporator coil and possibly liquid flooding back to the compressor.

There are several ways a technician can measure the airflow across an evaporator. Two common methods are (1) measuring the temperature rise across the indoor system (this does require the air-conditioning system to be attached to a forced-air furnace or air-handling unit and (2) measuring the static pressure drop across the evaporator.

TECH TIP

Measuring various types of temperatures is a common task for technicians. The thermometers used must be accurate for a technician to be able to properly work on air-conditioning systems. Technicians should occasionally test the accuracy of their thermometers.

Testing a thermometer can easily be accomplished by placing it in a solution of crushed ice and water. Fill a bucket with crushed ice and add water so that three-fourths of the ice is immersed in the water. It is best to have a solution that has more ice than water. Let the temperature of the solution stabilize, which should happen close to 32°F.

Once the temperature of the solution has stabilized, place the thermometer in the ice/water solution. Let the temperature measured on the thermometer stabilize, and observe its reading. If the thermometer measures a temperature relatively close to 32°F, then it is relatively accurate. If not, the thermometer needs to be adjusted, repaired, or discarded.

Temperature-Rise Method

When an air-conditioning system is attached to a forced-air furnace, the furnace can be used to calculate the airflow across the evaporator. By measuring the temperature rise across the furnace in the heating mode and with the fan operating at the same speed as it would during the cooling mode, the airflow across the device can be calculated.

To use this method, a technician would need to know the BTU output of the furnace and the temperature rise across the furnace (temperature rise = supply air – return air). To obtain the BTU output of a furnace, a technician would need to know the BTU input and its actual efficiency or AFUE rating. The following steps can be used to estimate airflow through a furnace and its evaporator coil.

- Step 1.** Obtain the BTU output of the furnace.
- Step 2.** Drill a hole in the return-air duct near the furnace and insert a temperature probe into the hole. Drill another hole in the supply-air duct, out of the line of sight of the heat exchanger, and place a temperature probe in the hole (Figure 45-23). Make sure the instruments used to measure the temperature at these two areas are calibrated to each other, meaning when exposed to the same temperature they read the same temperature.
- Step 3.** Turn the system on, call for heat, and operate the fan at the same speed that it would run at in the cooling mode. On some systems, this is as easy as placing the fan selector switch to the ON position. On many systems, the fan speed will be the same as during the cooling mode. On some newer systems, when the fan selector is switched to the ON position, the fan will operate at a continuous speed, which may not be the same speed as in the cooling mode. On these systems, the technician may need to rewire the fan to allow it to operate at the same speed when in the cooling mode.

Figure 45-23 Measuring the temperature rise across a forced-air furnace.

- Step 4.** Let the system run for 10 to 15 minutes so the temperatures can stabilize.
- Step 5.** Determine the temperature rise across the system by subtracting the return-air temperature from the supply air.
- Step 6.** The airflow through the furnace as well as the air conditioning coil can then be calculated using the equation:

$$\text{CFM} = \frac{\text{Btu output}}{1.08 \times \Delta T}$$

where

CFM = airflow volume measured in cubic feet of air per minute

BTU output = the rated heat output for the furnace measured in BTU/hr

1.08 = a constant for air under normal conditions at sea level (sometimes 1.1 is used for this value)

ΔT = the temperature difference between entering and exiting air, sometimes expressed as $(T_1 - T_2)$

For example, suppose a technician is working on a 3-ton air-conditioning system with a forced-air furnace with a BTU output of 80,000 BTU. When operating in the heating mode with the fan selector switch at the ON position (the fan will operate at the cooling speed), a technician measures a supply-air temperature of 137°F and a return-air temperature of 75°F. The temperature rise across the system would be 62°F (137°F – 75°F = 62°F). Then the airflow through the furnace and the evaporator coil can be calculated as:

$$\text{CFM} = \frac{\text{Btu output}}{1.08 \times \Delta T}$$

$$\text{CFM} = \frac{80,000 \text{ Btu}}{1.08 \times 62^\circ \text{F}}$$

$$\text{CFM} = 1,194.7$$

This will yield an estimated airflow value of 1,194.70 CFM across the evaporator coil. This is reasonably close to the desired value of 1,200 CFM, concluding that the airflow across the evaporator is sufficient.

Measuring the Static Pressure Drop Across an Evaporator

Another way a technician can measure the airflow across an evaporator is by measuring the static pressure drop across the evaporator coil. As air flows across an evaporator coil, it will lose some of its static pressure. As the volume of air flowing across the evaporator coil increases, so will its static pressure drop (loss). Equipment manufacturers publish specifications on the static pressure drop created by a volume (CFM) of air flowing across their evaporator coils. If the static pressure drop across an evaporator coil were measured, a technician could use the published specifications from a manufacturer to determine the actual airflow across the evaporator coil. Manufacturers will publish two different static pressure values: one for when the coil is dry and another for when the coil is wet. This is because there

Figure 45-24 Measuring the static pressure drop across an evaporator coil.

is a difference in the resistance to airflow across a dry and a wetted coil.

To calculate the pressure drop across an evaporator coil, a technician will need to measure the static pressure at the inlet and the outlet of the coil. The pressures to be measured are relatively small, so a technician will need to use an inclined manometer, which has a range approximately of 0.00 in wc to 1.00 in wc.

Figure 45-24 shows a typical setup for measuring the static pressure drop across a coil. The steps for measuring the static pressure drop across an evaporator coil are:

Step 1. Drill a 1/4-in hole on either side of the evaporator coil. Always refer to the manufacturer's instructions for the recommended location of

these holes. *Be extremely careful not to drill into the evaporator coil*—this will take a rather simple task and turn it into a nightmare for a technician.

Step 2. Insert a 1/4-in tube into each hole far enough so that it will measure the static pressure on each side of the coil. Seal the insertion point of each tube and connect to a manometer, as shown in Figure 45-24. Connect the inlet side of the evaporator coil to the lower end of the manometer, and connect the outlet side of the evaporator to the higher end of the manometer. Keep in mind that it is critical that the inserted tubes be held so they are perpendicular to the flow of air to avoid having the measurement tainted by velocity pressure. Use of a pitot tube or static pressure probe can prevent this possibility.

Step 3. Turn the indoor blower on and let it run for a few minutes so the airflow within the system can balance.

Step 4. Read the static pressure drop directly from the manometer.

Step 5. Using the information provided by the equipment manufacturer, read the amount of air flowing across the evaporator directly off the chart. Remember there will be a different value depending on whether the coil is dry or wet.

For example, a technician needs to determine the actual amount of air flowing across a dry 3 ton evaporator coil. The coil's model number is 036 and the measured static pressure drop is 0.18 in wc. Using the sample chart in Table 45-1, the airflow is determined to be 1,200 CFM. The conclusion is that the airflow is correct.

Table 45-1 Sample Performance Data: Coil Static Pressure Drop (in wc)

Unit Model	Air Quantity (CFM)													
	400	500	600	700	800	900	1,000	1,100	1,200	1,300	1,400	1,500	1,600	1,700

□ Wet coil

■ Dry coil

TECH TIP

Most manufacturers recommend that a system's airflow be set so that there is approximately 400 CFM per ton of air conditioning. In areas that have high relative humidity, a slightly slower fan speed can be used to aid in the dehumidification. In arid areas, the fan speed can be increased to provide more sensible cooling. As a rule of thumb, the fan speed should not be adjusted more than 10 percent above or below the manufacturer's recommendation. Excessively slow fan speeds can allow the evaporative coil to freeze up under light loads, and excessively high fan speeds can put too large a load on the condenser under heavy load conditions.

Checking and Adjusting the Refrigerant Charge

There are several methods a technician can use to determine the correct refrigerant charge of a residential split-system air conditioner. A technician should always first refer to the installation instructions and use the method recommended by the equipment manufacturer.

Many new residential condensing units are shipped from the factory with a refrigerant charge. The amount of refrigerant contained in the condensing unit will vary depending on its size and the manufacturer's engineering principles. Most manufacturers will ship their condensing units with enough refrigerant to properly operate a system with a 15-ft line set. This means that if there is 15-ft of suction line and liquid line between the condensing unit and the evaporator, no additional refrigerant will need to be added to the system. Always check the installation instructions of the condensing unit, as some manufacturers will add enough refrigerant for a different line length. If a system is installed with a line set greater than 15 ft (or the length stated in the installation instructions), the technician will need to add additional refrigerant to the system. The installation instructions will state the amount of refrigerant that needs to be added per foot of additional run of the liquid line used. Some manufacturers will also state the amount of additional refrigerant needed for the extended suction line, but this is normally a small amount and many times is omitted by the manufacturer.

For example, a new system is installed with a 25-ft line set, using a $\frac{3}{8}$ -in liquid line. According to the manufacturer's instructions, the factory charge is adequate for a 15-ft line set. For each additional foot of $\frac{3}{8}$ -in liquid run, there will need to be 0.6 oz of additional refrigerant added. As an example, if the length of the additional liquid line is 10 ft ($25 \text{ ft} - 15 \text{ ft} = 10 \text{ ft}$), then 6 oz ($10 \times 0.6 = 6 \text{ oz}$) of additional refrigerant will need to be added to the system.

For a system using a fixed restriction metering device, such as a fixed orifice, there is another means of determining if a system has an adequate refrigerant charge. This can

be accomplished by measuring the superheat value of the refrigerant at the suction line leading into the condensing unit. The superheat value is not a constant value and varies at different indoor and outdoor ambient conditions. Manufacturers will publish a chart showing the required superheat value at various indoor and outdoor ambient conditions. If the actual measured superheat value is within $\pm 5^\circ\text{F}$ of the required superheat value, the system is properly charged. If the actual measured superheat value is more than 5°F higher than the required superheat value, refrigerant needs to be added to the system. If the actual measured superheat value is more than 5°F lower than the required superheat value, refrigerant needs to be removed from the system.

For systems using a TEV metering device, there is another means of determining whether the system has an adequate refrigerant charge. This can be accomplished by measuring the subcooling value of the refrigerant at the liquid line leaving the condensing unit. Generally, a system is properly charged if the refrigerant is subcooled by 12 to 15°F at this location. Always check with the manufacturer of the system for their requirements. If the actual measured subcooling value is within $\pm 3^\circ\text{F}$ of the required subcooling value, the system is properly charged. If the actual measured subcooling value is more than 3°F lower than the required subcooling value, refrigerant needs to be added to the system. If the actual measured subcooling value is more than 3°F higher than the required subcooling value, refrigerant needs to be removed from the system.

When using either the subcooling or superheat methods of checking the refrigerant charge, allow the system to run approximately 15 minutes before measuring these values. This will allow the system's pressures and temperatures to stabilize so that an accurate reading can be obtained.

45.10 BEFORE YOU LEAVE THE JOB

Even after the installation is complete, the technician's job is not over. The work area should be completely cleaned. This includes wiping down the casing of the indoor and outdoor equipment as well as the thermostat. Any unused material needs to be removed from the property. If any of the customer's items were moved during the installation process, they would need to be returned to their original locations.

The technician should show the customer the complete system and explain its operation. This includes how to operate the system's thermostat and where the system's electrical disconnects are located. The technician should also explain any required maintenance, such as changing the filter and cleaning the outdoor condensing unit, and explain the system's warranty in detail.

After explaining the operation of the system and explaining the system's warranty, the technician should ask the customer if they have any questions, place a company sticker on the unit, and thank them for using their company. If a "use and care" manual is provided by the manufacturer, it should be given to the customer.

TECH TIP

The actual total BTU capacity of an air-conditioning system can be determined by measuring the airflow across the evaporator and the enthalpy difference of the air entering and leaving the evaporator. Then using the equation $\text{BTU capacity} = 4.50 \times \text{CFM} \times \text{enthalpy difference } (\Delta H)$, the actual total BTU capacity can be determined.

The enthalpy difference of the air entering and leaving the system's evaporator can be determined by first measuring the wet-bulb temperature of the air entering and leaving the evaporator. Then, using a psychrometric chart, the enthalpy content of the air entering and leaving the evaporator can be determined.

For example, if the wet-bulb temperature of the air entering the evaporator is 66°F, its enthalpy content will be 30.8 BTU/lb. And if the wet-bulb temperature of the air leaving the evaporator is 57°F, its enthalpy content will be 24.5 BTU/lb. The enthalpy difference will then be 6.3 (30.8 – 24.5).

If the airflow across the evaporator were measured at 1,210 CFM, then using the equation $\text{BTU capacity} = 4.50 \times \text{CFM} \times \text{enthalpy difference}$, the BTU capacity of the system would equal approximately 34,304 BTU = $(4.50 \times 1,210 \text{ CFM} \times 6.3 \text{ BTU/lb})$.

UNIT 45—SUMMARY

The success of any installation lies in its planning. Part of the planning procedure requires a technician to reference the manufacturer's installation manual and determine the installation requirements of the system. There are two types of installations for the indoor section: cased/uncased evaporator assemblies and air handlers. The location of an outdoor condensing unit is an important part of the overall installation process.

Before installing the refrigerant lines, make sure the metering device installed in the indoor unit is correctly sized for the application. Do not exceed the maximum line set length as stated by the manufacturer; generally, pipe runs can be up to 175 ft. If the line set exceeds approximately 50 ft or a distance specified by the manufacturer, special modifications will need to be done to the system.

A standing pressure test is normally used to check for refrigerant leaks. Once the system is leak tested and is determined leak free, the system needs to be evacuated to 500 microns or less.

When installing residential air-conditioning systems, the installing contractor must be sure the appropriate type of overcurrent protection device is used with the outdoor condensing unit. The evaporator drain pan will normally have both a primary and a secondary drain. For attic or ceiling installations, it is advisable to install an additional drain pan under the fan coil to prevent water damage caused by an overflowing condensate line. There should be approximately 400 CFM per ton of airflow across the evaporator.

The correct refrigerant charge of a system can be determined by weighing the correct additional amount of refrigerant, measuring the superheat value of the refrigerant in the suction line at the inlet of the condensing unit, and measuring the subcooling value in the liquid line at the outlet of the condensing unit. For systems using a non-TEV metering device, the superheat method should be used to determine if a system has an adequate refrigerant charge. For systems using a TEV metering device, the subcooling method should be used to determine if a system has an adequate refrigerant charge.

After the installation is complete, the technician's job is not over. The work area should be completely cleaned and the system's operation and warranty explained to the customer.

WORK ORDERS

Service Ticket 4501

Customer Complaint: System Not Cooling Properly

Equipment Type: 3-Ton, 13-SEER R-22 Residential Split-System AC

Last week this new system was connected to an existing 80,000-BTU output forced-air furnace. This week the customer called complaining that the system is not cooling properly. A technician is called out to check the system.

When the technician arrives on the job, the outdoor condensing unit and indoor blower are running. After further investigation, the following conditions are observed:

- The outdoor ambient temperature is 95°F.
- Air filter is clean.
- Indoor blower is clean.
- Evaporator coil is clean.
- Condenser coil is clean.
- 208 V is measured at the common and run terminals of the compressor.
- Suction pressure is 76 psig.
- Discharge pressure is 275 psig.
- The wet-bulb temperature entering the evaporator is 70°F.
- A suction line temperature at the inlet of the compressor is 63°F.
- With the heating system turned on and with the fan running at the cooling speed, a temperature rise of 61°F is measured.

The technician then decides the system is operating normally and discusses the system's operation with the customer.

Service Ticket 4502

Customer Complaint: System Not Cooling Properly

Equipment Type: 3-Ton, 14-SEER R-410A Residential Split-System Air Conditioner

Last week this new system with a fixed orifice was connected to an existing 80,000-BTU output forced-air furnace. This week the customer called complaining that

the system is not cooling properly. A technician is called out to check the system.

When the technician arrives on the job, the outdoor condensing unit and indoor blower are running. After further investigation, the following conditions are observed:

- Air filter is clean.
- Condenser coil is clean.
- Return air temperature is 79°F db and 64°F wb.
- System's supply air temperature is 69°F.
- Outdoor ambient temperature is 85°F.
- Suction pressure measured at the compressor is 105 psig.
- Suction line temperature at the inlet of the compressor is 65°F.
- Discharge pressure measured at the compressor is 330 psig.
- Discharge-line temperature at the compressor is 195°F.
- Liquid-line temperature at the outlet of the condenser is 99°F.
- Temperature rise across the furnace in the heating mode with the fan operating at the cooling speed is 65°F.

The technician then decides the system is operating with a low refrigerant charge and begins searching for the source of the leak.

Service Ticket 4503

Customer Complaint: System Not Cooling Properly When Outdoor Temperature Is High

Equipment Type: 2-Ton, 13-SEER R-22 Residential Split-System Air Conditioner

Last week this new system with a fixed orifice was connected to an existing 60,000-BTU output forced-air furnace. This week the customer called complaining that the system is not cooling properly when the outdoor temperature is high. A technician was called out to check the system.

When the technician arrives on the job, he discovers the outdoor condensing unit and indoor blower are running. After further investigation, the technician observes the following conditions:

- Outdoor ambient temperature is 95°F db.
- Return-air temperature is 70°F WB and 85°F db.
- Evaporator coil is clean and free of frost or ice.
- Filter is clean.
- Suction pressure is 80 psig.
- Discharge pressure is 305 psig.

- Suction-line temperature is 78°F.
- Liquid-line temperature is 121°F.
- Supply-air temperature at the outlet of the evaporator is 66°F db.

The technician then decides the system is operating with a high evaporator load, most likely due to an undersized air-conditioning system.

UNIT 45—REVIEW QUESTIONS

1. Why is it important to properly plan the installation of a residential split-system air conditioner?
2. What should a technician reference before installing a system?
3. What is the industry standard for determining the heat gain of a residential structure?
4. What happens if a system is oversized for its application?
5. What is the minimum SEER rating for new systems?
6. What is the name of the outdoor rated, watertight, flexible electrical cable connecting the system's disconnect to the condensing unit?
7. What gauge thermostat wire is typically used on residential systems?
8. Where should an outdoor condensing unit not be located?
9. Normally, what is the maximum length a line set can be run on many residential split-system air conditioners?
10. How should a technician determine the diameter of the line set to use?
11. Why are sections of tubing that are to be fitted together sometimes swaged?
12. What micron level should be achieved when evacuating a system?
13. What are the three main types of overcurrent protection devices that can be used on a condensing unit?
14. At what height should a thermostat be mounted above the floor?
15. What diameter condensate line is typically run from the drain pan of the evaporator?
16. What is the purpose of the secondary drain line?
17. What is the required airflow across the evaporator of a residential split-system air conditioner?
18. What two methods can be used to measure the airflow across an evaporator?
19. For a system using a non-TEV metering device, such as a fixed orifice, what method can be used to determine if the refrigerant charge is adequate?
20. When the installation is complete, what should a technician do before leaving the job?

UNIT 46

Duct Installation

OBJECTIVES

After completing this unit, you will be able to:

1. list the agencies that set standards for duct systems.
2. explain the difference between a flexible duct and a flexible connector.
3. list the materials used to construct duct systems.
4. explain how to seal duct systems.
5. describe how to join different types of duct.
6. discuss how to measure the amount of duct leakage.
7. describe the three methods of quantifying duct leakage rates.

46.1 INTRODUCTION

Duct systems are the distribution network for conditioned air to be moved throughout a building. Technicians need to understand duct systems and airflow to be able to troubleshoot and maintain HVACR systems. The most common materials used for duct construction include galvanized steel, fiberglass ductboard, and wire-helix flexible duct. Regardless of the materials used, a correctly installed duct system should last as long as the house, should not leak, and should be insulated well enough to prevent duct loss and gain to unconditioned space.

46.2 AIR-DISTRIBUTION SYSTEM COMPONENTS

Forced-air systems are used to distribute conditioned air in residential and small commercial buildings. Air is conditioned and distributed through the duct system throughout the building. The basic components of a forced-air system are the blower, the return-air ductwork carrying air to the blower, and the supply-air ductwork carrying air from the blower to the building.

Most systems have large boxes on both the return and supply ends of the blower called plenums (Figure 46-1). The plenum distributes the air to the ductwork attached to it. The duct design can be compared to a tree: the main ducts leaving the plenum are called trunk ducts, and the individual ducts running to each room are called branch ducts. The point where a branch duct comes off of a trunk duct is called a takeoff.

The duct openings to the conditioned space are covered by registers, diffusers, or grilles. The return-air openings are covered by return-air grilles. The supply-air openings are covered by supply-air registers. They direct the airflow into the room. These are sometimes called diffusers because they spread, or diffuse, the air.

Between the blower and the diffuser, the airstream must change direction and shape. This is accomplished with duct fittings. Turns are made with elbows, often called ells (Figure 46-2). A wye fitting is used to split one large duct into two smaller ducts (Figure 46-3). A change in the

Figure 46-1 The supply and return plenums are connected on either end of the indoor blower. (Courtesy of Stanfield Air Systems)

size of a rectangular duct is accomplished with a transition (Figure 46-4). A change in the size of a round duct is done with a reducer (Figure 46-5). When the register at the end of a round branch duct is rectangular, a fitting called a boot is used to allow the round duct to connect to the rectangular register (Figure 46-6).

The blower provides the pressure difference to move the air through the ductwork. The amount of air the blower can move and the amount of energy needed to move the

Figure 46-2 Elbows are used for turns in the ductwork.

Figure 46-3 A wye is used to split one large duct into two smaller ducts.

Figure 46-4 A transition is used to change rectangular duct from one size to another.

Figure 46-5 A reducer is used to change round duct from one size to another.

Figure 46-6 A boot is used at the end of a round duct to allow connection of a rectangular register or grill.

air is controlled by the resistance to airflow from the ductwork and all the system components in the airstream. The duct offers resistance to airflow, creating a pressure drop as the air travels through it. Besides the ducts, every component that the air travels through adds pressure drop. This includes filters, humidifiers, heat exchangers, coils, registers, and grilles. The amount of pressure left for moving air through the ductwork is the difference between the amount of pressure the fan can produce and the amount of pressure drop from all these system components. Figure 46-7 shows the components of a forced-air system and the pressure drop created across each component.

46.3 DUCT LOCATION

The three most common areas to locate the duct system are in the attic, in the space between the joists in the ceiling or between floors, and under the building in either the basement or crawlspace. The structure and layout of the building determine the available location for system components. The building's design affects the air-handler location, which then controls the duct system layout. The

Figure 46-7 Basic components of a forced-air system.

duct location will determine the amount of duct insulation required. The building's designer may specify the layout or may leave it up to the air-conditioning contracting company.

For maximum system efficiency, the duct system should be located so that it is within the building's insulation envelope (Figure 46-8). In a residence with a full basement,

Figure 46-8 Duct installed in joist space so it is inside the building envelope.

the basement is an excellent location for the trunk ducts and air-conditioning equipment. Equipment can also be located in a closet space or utility room. All enclosures must meet local fire and safety codes.

TECH TIP

A number of studies have shown that traditional duct-installation practices can result in systems that have excessive air leaks. New codes require the use of UL 181–approved duct tapes and UL 181–approved mastics to reduce air leaks and improve system efficiencies.

It is not always possible to locate the ducts within the building's envelope. For slab construction, ducts and even equipment can be placed in the attic. However, an attic duct system is a particularly poor choice for an air-conditioning system in a warm climate. Ducts located in unconditioned areas must be properly insulated, and an allowance must be made for heat loss included in the load calculation. Energy-efficiency guidelines require that ducts located outside of the building's envelope have R8 insulation value. Ducts for perimeter (heating only) systems can be located in the slab.

Before beginning the duct system layout and design for any building, check with the local building department, county, or state code and/or regulatory agencies to determine the specific insulation requirements for the building's type and location.

46.4 EQUIPMENT TYPES

The design of the duct system is affected by the type of equipment selected. Forced-air equipment is typically either packaged equipment or a split system. With packaged equipment, the entire system is located outside the structure and the ductwork is typically located in the basement or crawlspace (Figure 46-9).

Split systems consist of an inside blower and an outside condensing unit. Split systems offer more flexibility in duct location because of the many possible blower locations. The blowers can be upflow, downflow, or horizontal.

Figure 46-9 Packaged air-conditioning unit with ductwork in crawlspace.

Figure 46-10 Upflow blower in the basement with all ducts in the basement.

The name describes the direction of airflow. Five common split-system duct configurations are as follows:

- Upflow blower in the basement with all ducts in the basement (Figure 46-10)
- Upflow blower located in the house with supply ducts located in the attic and return in the house (Figure 46-11)
- Downflow blower in the house with supply ducts in the crawlspace and return in the house (Figure 46-12)
- Horizontal blower in the crawlspace with all ducts located in the crawlspace (Figure 46-13)
- Horizontal blower located in the attic with all ducts located in the attic (Figure 46-14)

Figure 46-11 Upflow blower located in the house with supply ducts located in the attic and return in the house.

Figure 46-12 Downflow blower in the house with supply ducts in the crawlspace and return in the house.

Figure 46-13 Horizontal blower in the crawlspace with all ducts located in the crawlspace.

Figure 46-14 Horizontal blower located in the attic with all ducts located in the attic.

46.5 DUCT SYSTEM TYPES

The four most common duct configurations are radial, reducing radial, extended plenum, and reducing extended plenum. Two less common types are the perimeter loop system and the central plenum system.

Radial Duct Systems

Radial duct systems are designed so that all or almost all of the duct runs originate at the central plenum. In some cases, a few of the duct runs may have wyes or duct triangles as a means of joining additional ducts to an initial run (Figure 46-15). Radial systems are most frequently installed in attics, but they can also be installed in crawlspaces and basements. Radial systems are commonly used in small houses built on concrete slabs.

Figure 46-15 Radial duct system.

Figure 46-16 Reducing radial duct system.

Reducing Radial Duct Systems

A reducing radial system uses several larger ducts leaving the main plenum that branch into smaller ducts as they get closer to their destination (Figure 46-16). This reduces the connections at the plenum and reduces the overall amount of duct used.

Extended Plenum

The extended-plenum duct system uses a large trunk duct that travels the length of the building from the air handler. These systems are sometimes referred to as trunk duct systems (Figure 46-17). The trunk duct is considered an extension of the plenum. The trunk ducts in extended plenum systems do not reduce in size as they travel across the structure. Extended plenum systems can be located in the crawlspace, attic, or basement.

Reducing Extended Plenum

The trunk ducts in the reducing extended-plenum system reduce in size (Figure 46-18). Typical reducing-plenum trunk ducts will reduce after every three to four takeoffs. Not only does this save material cost, but it makes the duct system work better. The air velocity in the trunk drops as the volume of air traveling through the trunk drops. Reducing the size of the trunk duct restores the velocity of the air in the trunk duct. This helps keep the static pressure throughout the system more even, aiding in more even air distribution.

Figure 46-17 Extended plenum duct system.

Figure 46-18 Reducing extended plenum duct system.

Figure 46-19 Perimeter loop duct system.

Perimeter Loop System

The perimeter-loop duct system uses radial feeder ducts from the blower that attach to one trunk that is installed around the outer edge of the foundation. Each supply is tapped off this trunk to provide equal airflow throughout the structure (Figure 46-19). Perimeter-loop systems are normally installed in concrete foundations and have the added efficiency of heating the slab. The duct for a perimeter-loop system must be placed before the slab is poured. These systems are generally used in single-story commercial office buildings built on slabs.

Central Plenum System

The central plenum duct system uses structural cavities as a pathway for supply- or return-air plenums. The basement, crawlspace, or space between floor joists can all serve as the plenum. Air is blown into the cavity, and holes are cut through the floor into the plenum cavity wherever a register is needed. To ensure proper operation of a plenum system, the cavity must be airtight and configured in a way that the airflow is not compromised.

This system is used because of its low cost. This system may not meet mechanical codes in some jurisdictions. Indoor air quality is a major concern due to the nature of these cavities. Moisture, mold, and odors are often hard to control.

46.6 DUCT MATERIALS

Air ducts can be made from many different materials. The most common types of ductwork are galvanized-steel sheet metal, spiral metal, fiberglass ductboard, flexible duct, and fabric duct.

Figure 46-20 Sheet metal is supplied in large sheets, which can be used to fabricate sheet-metal ductwork.

Galvanized Sheet Metal

Sheet metal can be fabricated into most any shape imaginable by a skilled sheet-metal worker. Galvanized sheet steel comes in large, flat sheets (Figure 46-20). Common sizes are 4 ft wide and 8–10 ft long, but other sizes are available depending upon the steel supplier. Sheet metal offers the least amount of resistance to airflow of any duct material because of its smooth surface.

Many localities adopt the metal duct standards developed by the Sheet Metal and Air Conditioning Contractor’s National Association (SMACNA). The thickness of the metal is called its gauge. A guideline for selecting metal thickness is shown in Figure 46-21.

For many years, galvanized sheet steel was used exclusively for air-conditioning ductwork because of its workability and durability. However, the material is expensive and costly to install, so other types of duct material have become popular. These include spiral metal duct, fiberglass ductboard, and flexible duct.

Figure 46-22 Spiral metal duct system.

Spiral Metal Duct

Spiral duct is made from long strips of narrow metal and fabricated with spiral seams (Figure 46-22). Machines are available for making ducts on the job to fit required diameters and lengths. Spiral metal duct is used in commercial applications. It is frequently used where the ductwork will be exposed. It requires less support than other types of duct due to its inherent rigidity.

TECH TIP

The UL 181 standard covers factory-made ducts and air connectors. All fiberduct and flexible duct should be UL approved and meet the UL 181 standard.

Fiberglass Ductboard

Fiberglass ductboard is a rigid material made of compressed fiberglass with an outer vapor barrier (Figure 46-23). It comes

	Comfort Heating or Cooling			Comfort Heating Only

14 in or less	0.019	28	24	—
Over 14 in	0.022	26	23	—

Figure 46-21 Gauges recommended for sheet-metal ductwork.

Figure 46-23 Fiberglass fiberduct comes in large sheets and can easily be fabricated into duct.

in 1-in, 1½-in, and 2-in thicknesses. Fiberglass ductboard has the advantage of being an inherently good insulator for both heat and sound. This reduces the duct losses and provides sound-absorbing qualities. Fiberglass ductboard is less expensive than metal, and fabricating ductboard duct is generally easier to work with than fabricating sheet metal duct. Ductboard is less durable than sheet metal duct and has a higher resistance to airflow than sheet metal because of its rougher interior surface.

Flexible Duct

The most common duct material used today in residential duct systems is undoubtedly flexible duct. Flexible duct has a spiral metal wire for support, a smooth plastic inner liner, an outer cover that serves as a vapor barrier, and fiberglass insulation sandwiched in between the inner liner and outer cover (Figure 46-24). The outer cover is typically vinyl or Mylar. Flexible duct comes in 25-ft lengths compressed in a box that is about 3 ft long. When opened it expands lengthwise into ducts (Figure 46-25).

SERVICE TIP

It is very important to stretch flex duct before installing it. Leaving the duct slack can easily double the duct's resistance to airflow. Allowing extra length in the duct run is a particularly bad practice that may save time during installation but will significantly reduce the airflow through the duct.

Figure 46-24 Flex duct is made of a helix wire for support, an inner liner, fiberglass insulation, and an outer vapor barrier.

Figure 46-25 Flexible duct comes compressed in a box and expands when removed from the box.

Flex duct is very popular because it is the least expensive duct material and the easiest to install. Unfortunately, it is also the easiest to install incorrectly. Common problems with flex duct include tight radius turns and improper support. Many poorly installed flex duct jobs have given the material a bad name. However, it is possible to install a good duct system with flex duct by following the manufacturer's installation instructions. Flex duct is very quiet because its soft sides absorb sound. However, the soft, undulating sides also have the highest resistance to airflow of all of the most commonly used duct materials.

46.7 STANDARDS

Approved methods of manufacturing, installing, and sealing ductwork are published by several national agencies that publish codes, standards, and guides. These standards are often referenced in state and local codes. Organizations publishing duct standards include the following:

- Underwriters Laboratories
- National Fire Protection Association
- Sheet Metal and Air Conditioning Contractors National Association

- North American Insulation Manufacturers Association
- Air Diffusion Council
- Air Conditioning Contractors of America.

Underwriters Laboratories

Underwriters Laboratories Standards 181, 181A, and 181B are probably the most referenced duct standards. Any manufactured duct should comply with UL 181 standards. Standard 181 covers manufactured duct materials, such as fiberglass ductboard and wire-helix flexible duct. Two classes of manufactured duct are listed according to their flammability: Class 0 and Class 1. Class 0 ducts have a flame spread index of 0. Class 1 ducts have a flame spread index not over 25 and a smoke developed index of not over 50. The flame spread index is a number relating to ASTM E 84 flammability testing. A rate of 100 is assigned to untreated bare wood, while 0 is assigned to cement board. The smoke developed index compares the amount of smoke produced compared to concrete, at 0, and red oak, at 100.

Many mechanical codes require that mastic and tape be UL 723 rated for metal duct. UL 723 tests materials for flame spread and smoke development. Materials that are UL 723 rated can be used on and in air plenums. UL Standard 181A addresses closure and sealing systems for manufactured rigid ducts, such as fiberglass ductboard. UL Standard 181 B addresses closure and sealing systems for flexible ductwork. Note that a tape may be UL rated but not meet 181 standards. A tape that only displays the 723 rating and not the 181 rating is not intended for ductboard or flex. Figure 46-26 shows the marking on UL-rated duct tape and mastic.

National Fire Protection Association

The NFPA publishes two standards that are widely referenced: 90A and 90B. Standard 90A covers the installation of ventilation and air conditioning, while 90B covers the installation of warm-air heating and air conditioning. Both standards discuss the types of materials that may be used for ductwork and discuss the application difference between flexible air duct and flexible air connector. Air ducts must either be made of rigid, nonflammable materials, like sheet

metal, or be tested and shown to meet the UL 181 standard. Flexible duct connectors are not certified to meet every provision of UL 181; therefore, their use is more limited.

Sheet Metal and Air Conditioning Contractors National Association

SMACNA publishes several duct and installation standards. The most commonly referenced is *HVAC Duct Construction Standards—Metal and Flexible*. It covers a lot of the nuts-and-bolts aspects of constructing and installing ductwork. Topics include duct joining, duct sealing, and duct hanging.

North American Insulation Manufacturers Association

NAIMA represents the fiberglass industry. They publish a manual called *Fibrous Glass Residential Duct Construction Standard*. This standard covers both the standard for fiberglass ductboard materials and how the materials should be installed.

Air Diffusion Council

The ADC represents flexible duct manufacturers and publishes standards relating to flexible duct systems. The most referenced is the *Flexible Duct Performance and Installation Standards*, which gives specific instructions for properly installing flexible wire-helix duct.

Air Conditioning Contractors of America

ACCA publishes many manuals for designing and installing air-conditioning systems. For duct installation, *HVAC Quality Installation Specification* is the most relevant. This manual covers the components of a quality installation, including the duct system.

46.8 SHEET-METAL DUCT

Galvanized sheet-metal duct has been the gold standard of duct systems for years. No other duct material has a lower friction rate or is as durable as sheet metal. Unfortunately, nothing else comes close to the cost of sheet metal either. Sheet metal is still used, but its prominence in residential duct systems is waning because of its high cost.

Round Galvanized Duct

Round duct is shipped in bundles with one piece of duct tucked inside another. Each piece needs to have its longitudinal seam snapped together before use. Figure 46-27 shows a typical snap-lock seam.

Snap-lock round duct is typically available in sections of 3, 4, and 5 ft depending upon the material, gauge, and duct diameter. Table 46-1 shows the lengths available from one supplier.

One end of the duct is crimped, making its outside diameter slightly smaller than the regular duct diameter. A bead behind the crimp serves as a stop when inserting one duct into another (Figure 46-28). The crimps should be

Figure 46-26 Duct tape and mastic should be UL 181 approved.

Table 46-1 Duct Section Length in Feet

Diameter (in)	30 Ga.	28 Ga.	26 Ga.	24 Ga.	Aluminum	Stainless
4–10	5		5	5	4	4
12	5		5	5	4	4
14		3	5	5	4	4
16			3	3	4	4
18			3	3	4	4
20			3	3	4	4
24			3	3	4	4

**Figure 46-27** Snap-lock seam on round galvanized duct.**Figure 46-28** The crimped end on a round piece of galvanized duct.**Figure 46-29** Airflow should be toward the crimped end of the duct.

installed in the direction of airflow to reduce turbulence (Figure 46-29). All joints should be fastened with sheet-metal screws or rivets. Ducts 10 inches in diameter or smaller should have at least three equally spaced screws or rivets per joint. Larger ducts should have at least four equally spaced screws or rivets per joint. The quantity of screws may vary depending on the inspection authority in your area.

These joints are not airtight and need sealing. The outer insulation around the pipe does not help seal in the air. Take apart an older system with unsealed joints and there is a black line in the duct wrap where the joint was (Figure 46-30). This black ring is formed by tiny dirt particles that were caught in the fiberglass as air leaked out of the joint. Tape and/or mastic are required to make these joints airtight.

**Figure 46-30** The stain on the duct wrap is caused by small dust particles escaping the leaky duct joint and getting caught in the duct insulation; it shows where the duct leaks air.

Figure 46-31 Wrinkles in duct tape can cause air leaks.

One method of sealing these joints is to use two wraps of UL 181A duct tape. The problem with this method is that little wrinkles are invariably left in the tape, and small amounts of air can escape through the wrinkles (Figure 46-31).

The preferred method is to use either mastic alone or tape and mastic. Mastic works fine by itself, provided that the cracks being sealed are not too large. Large cracks can be covered with UL 181A duct tape first and then covered with mastic.

Rectangular Galvanized Duct

Rectangular duct typically is made in two L-shaped pieces. Each piece has one duct width and one duct height (Figure 46-32). These pieces are normally joined by either a snap-lock joint or a Pittsburgh joint. The 0.25-in edge of the snap-lock snaps down into the seam. Typically it is hammered down using a sheet-metal hammer (Figure 46-33). The ¼-in edge in a Pittsburgh seam fits into the seam and the edge of the seam is hammered over (Figure 46-34). The Pittsburgh joint is more airtight but takes more material and time to produce.

Figure 46-32 Rectangular duct before assembly.

Figure 46-33 Hammering in a snap-lock seam on rectangular duct.

Rectangular ducts are joined by S-locks and drive cleats. An S-lock is a piece of sheet metal in a flattened S-shape. One duct slides into the S-lock in one direction and the other duct slides into the S-lock from the other direction (Figure 46-35). S-locks are used on the larger duct dimension, usually the top and bottom. The shorter dimensions are joined by drive cleats. The duct edges are turned back and the drive cleat slips over the edges and pulls the duct together (Figure 46-36). These are driven down with a mallet; thus the name “drive cleat.” These joints are not airtight and need to be sealed, preferably with UL 181A mastic or UL 181A tape and mastic.

Hanging Metal Duct

One advantage of metal duct is that it has structural integrity, making it much easier to hang than flexible duct. Hangers should be spaced no farther than 12 ft apart. Many materials can be used as hangers, including wire, plumber's strap, or sheet-metal strips. Any screws that are run into the duct to fasten the hanger to the duct should be covered with mastic. When possible, long sections of metal duct are assembled on the ground and hung as a section. This makes it easier to assemble straight runs. Frequently these sections are also insulated before being hung. Attaching the duct one piece at a time while hanging the duct is much more difficult. Likewise, insulating while working around the hangers is more difficult than when the section of duct

Figure 46-34 Hammering a Pittsburgh seam on rectangular duct.

is on the ground and can be freely moved around. Figure 46-37 shows properly supported duct.

Takeoffs

The first step in installing a takeoff is to cut a hole in the duct. The easiest, fastest, and cleanest method for cutting a round hole in the duct is to use an adjustable hole cutter (Figure 46-38). The hole cutter is set to the size of the hole needed. A drill is attached to the hole-cutter bit. First, drill a hole where the center of the hole will be. Next, place the hole cutter's pivot point in the hole and cut a full circle using the drill.

Figure 46-35 The long sides of the duct are joined using S-locks.

Figure 46-36 The short sides are joined with drive cleats.

Figure 46-37 Properly supported and insulated galvanized duct system. (Courtesy of Stanfield Air Systems)

Figure 46-38 This hole was just cut using the adjustable hole cutter. (Courtesy of Malco Products, Inc.)

Figure 46-39 Duct-piercing tool.

Holes can also be cut using aviation snips. Hold a short piece of pipe the size of the takeoff up to the duct and draw its perimeter on the duct. Cutting this hole out is harder than it might appear at first. It is generally not possible to simply cut along the line in a circle. When sheet metal is cut with snips, one side must bend out of the way to let the snips pass by. Neither side can bend out of the way on a piece of duct. Two solutions are (1) making a spiral cut from the center and (2) using a duct-piercing tool to cut a line across the diameter of the hole and cutting out each semicircle.

For the spiral cut, a starter hole should be struck in the center using a duct-piercing tool (Figure 46-39). Cut in an increasing spiral using either left-hand or right-hand aviation snips (Figure 46-40). Continue to follow the line once the spiral reaches it.

For the semicircle cut, use a duct-piercing tool to cut across the diameter of the hole (Figure 46-41). Then use left- or right-hand aviation snips to cut out each semicircle (Figure 46-42).

Takeoffs are connected to metal duct using either dovetails or flanges. Dovetail fittings have tabs that are formed

Figure 46-41 Slicing the diameter of a circle using a duct-piercing tool.

Figure 46-42 Once the diameter has been sliced, the circle can be cut in two semicircular sections.

by a series of slits along the perimeter of the fitting (Figure 46-43). Every other tab is turned 90° to the fitting (Figure 46-44). The straight tabs are inserted into the hole, and the technician reaches through the hole and bends the straight tabs over. Sheet-metal screws are run through three or four

Figure 46-40 Round holes can be cut using a spiral pattern.

Figure 46-43 Traditional dovetail takeoff.

Figure 46-44 The tabs of the dovetail fitting folded over.

evenly spaced tabs to securely hold the fitting in place. The intersection of the collar and ductwork is sealed with mastic. This is particularly important with dovetail fittings.

Flange fittings have a flange that fits on the outside of the duct. Some flange takeoffs have a self-adhesive pad that attaches the fitting to the duct and seals it (Figure 46-45). If the flange is not self-sealing, mastic should be applied to the flange before placing the fitting against the outside of the duct. The fitting is held in place by three to four equally spaced sheet-metal screws run through the flange.

46.9 DUCT INSULATION

One major disadvantage of metal duct compared to duct-board or flex is that metal duct must be insulated. Round duct is insulated with duct wrap. The most common type of duct wrap is made of fiberglass with an outer vapor bar-

Figure 46-45 Flange take off with sticky pad.

rier of vinyl, aluminum foil, or aluminum foil reinforced with kraft-back paper. Duct wrap comes in 4-ft rolls. One side has 2 in of vapor barrier that is uninsulated. This edge laps over the edge of the insulation already on the duct, providing a continuous vapor barrier. When insulating duct, the duct wrap is pulled around the duct and lapped over itself. The insulation should be pulled tightly around the duct to eliminate gaps and sags in the insulation. But compressing insulation reduces its R value, so it should not be pulled so tightly that the fiberglass is flattened. The most common method for fastening the duct wrap is stapling it to itself. A clinch staple goes through both layers of insulation and turns back (Figure 46-46). The insulation should be stapled every 6 in for the entire length. The exposed outer edge is taped with a UL 181A tape that matches the vapor barrier. When the job is done, no metal should be showing, no fiberglass should be

Figure 46-46 Clinch staples hold insulation together by turning outward in each direction.

Figure 46-47 Properly insulated ductwork. (Courtesy of Stanfield Air Systems)

showing, and the vapor barrier should cover the entire duct system (Figure 46-47).

The duct wrap should be cut in pieces that are large enough to wrap around the duct and have some overlap. For round duct, this is typically the duct circumference plus an adjustment for the thickness of the wrap plus some overlap. The adjustment is 9.5 in for 1.5-in-thick wrap, 12

in for 2-in-thick wrap, and 17 in for 3-in-thick wrap. Table 46-2 shows the size that duct wrap should be cut for different diameter ducts and different thickness of duct wrap. For example, 2-in-thick insulation for a 7-in-diameter duct should be 34-in wide.

The same basic concept applies to rectangular duct, but the adjustments are not quite as large. The adjustments are 7 in for 1.5-in-thick insulation, 8 in for 2-in-thick insulation, and 11.5 in for 3-in-thick insulation.

Duct Liner

Rectangular duct, plenums, and return-air boxes may be lined with insulation rather than wrapped (Figure 46-48). Duct liner is also fiberglass, but it does not have a vapor barrier. Duct liner is glued to the inside of the duct and connected with mechanical fasteners that compress the insulation. The fasteners should start within 4 in of the end of the duct and continue every 18 in for the length of the duct. A new row of fasteners should be installed every 12 in across the width the duct.

Lining the duct makes a system quieter and is usually easier than wrapping the duct. A disadvantage of lining duct is increased resistance to air flow. One of the advantages of metal duct, low air resistance, is negated by lining it with fiberglass. Liner also tends to collect dust. After a period of years, the liner will end up looking like a dirty filter because the fiberglass grabs and holds tiny dust particles. When a liner is used, the duct must be made larger to compensate for the space the liner takes up. When using 1-in liner, the duct must be 2 in larger in both dimensions to allow for the thickness of the duct liner.

Bubble Wrap

Bubble wrap is a new form of duct insulation. It is similar to the bubble packing material with outer layers of either metalized Mylar or aluminum (Figure 46-49). Bubble wrap may be used as liner or as duct wrap. Bubble wrap is typically not applied directly to the duct. Spacers are

Table 46-2 Duct Insulation Dimensions (in inches)

Duct Dimensions		Insulation Thickness		
Duct Diameter	Duct Circumference	1.5 in (9.5-in Adjustment)	2 in (12-in Adjustment)	3 in (17-in Adjustment)
5	16	25.5	28	33
6	19	28.5	31	36

Figure 46-49 Duct insulated with bubble wrap.

Figure 46-50 Fiberglass ductboard.

applied to the duct and the bubble wrap is applied to the spacers. Installers like bubble wrap because it does not irritate their skin and cause itching like fiberglass does. However, it is a new product without the long track record of success that fiberglass has.

46.10 DUCTBOARD

One alternative to sheet-metal duct is ductboard. Ductboard is a rigid fiberglass insulating board with an outer vapor barrier used to construct plenums and ductwork (Figure 46-50). The inner wall does not have a covering, but the fiberglass is matted and stiff, not fluffy like duct wrap. Quality ductboard should be UL 181 rated, and the tapes used to fabricate it should be UL 181A rated. Compared to metal duct, ductboard has several advantages. It is relatively low in both material and installation cost, it does not need insulating because it is inherently thermally efficient, it is generally easier to fabricate, and it produces quieter systems.

Despite these advantages, many contractors still consider a ductboard duct system inferior to a metal duct system. It is less durable than metal but holds up well if fabricated correctly. Unfortunately, the industry has seen a lot of ductboard that was not fabricated correctly and did not last long. Ductboard has a higher resistance to airflow because of its relatively rough interior surface. This surface also causes it to collect dirt. Small dust particles entrained in the air lodge in the surface of the ductboard; after several years of service, the interior surface of most ductboard systems is black.

Fabrication

Ductwork is constructed by cutting grooves or slots in the fiberglass where each corner will be. The tools are hand tools with razor-sharp knife blades that cut through the fiberglass to form the joints. Types of joints used are the V-groove, shiplap, and modified shiplap (Figure 46-51). Enough fiberglass is cut out to allow the ductboard to fold and form corners. The last edge is cut to form a flap. The ductboard is then folded at these corners. The two edges of the ductboard are mated and the flap is folded over and

Figure 46-51 Types of ductboard joints.

secured using staples and UL 181A duct tape or just UL 181A duct tape. Pressure-sensitive and heat-activated tape are both available.

Pressure-Sensitive Tape

The edge of the flap should be positioned in the middle of the tape with a minimum overlap of 1 in on each side. Pressure-sensitive tape should be worked with a tool edge, not just not fingertip pressure. Rub tape firmly with a plastic sealing tool until the facing reinforcement shows through the tape. Avoid excessive pressure on the sealing tool that could cause the tape to be punctured at staple locations.

Pressure-sensitive tape should not be used below 50°F without heating. The duct must be preheated using an iron with the plate temperature set at approximately 400°F. Quickly position the tape on the preheated area and press in place. Pass the iron two or three times over the taped area using a rapid ironing motion. Complete the bond by rubbing the tape firmly with the plastic sealing tool until the facing reinforcement shows through the tape clearly.

Heat-Activated Tape

The edge of the flap should be positioned in the middle of the tape with a minimum overlap of 1 in on each side. The seaming iron should have a plate temperature of between 550°F and 600°F. Slowly pass the iron along the tape seam with sufficient pressure and dwell time to activate the adhesive. Heat-indicator dots on the tape will darken to indicate when a satisfactory bond has been achieved. Use a second pass of the iron to complete the bond. Avoid puncturing the tape at staple locations with excessive pressure from the iron. Allow all joints and seams to cool below a 150°F (66°C) surface temperature before any stress is applied.

SAFETY TIP

Always work with gloves and exercise caution to prevent burn injuries from contact with the iron or with heated surfaces. Even momentary contact with a 600° surface can cause a painful burn.

Figure 46-52 Joining ductboard sections.

Joining Ductboard Sections

Ductboard sections are joined to each other using a shiplap joint. The shiplap joint provides some structural rigidity to the joint. The sections are sealed using either pressure-sensitive or heat-activated tape (Figure 46-52).

Hanging Ductboard

Properly constructed, ductboard has good structural integrity. It is also lightweight, so hangers are not required to support a lot of weight. Duct hangers should be at least 1 in wide across the bottom. A common arrangement is to use an inverted 1-in metal channel that is suspended by wire, straps, or rods (Figure 46-53). Hangers should not be placed directly under joints between two pieces of duct to avoid stressing the joints. Hangers should be placed every 6 ft for duct that is less than 12-in high or every 8 ft for ducts that are 12-in high or larger. Duct should be suspended at least 1 in above ceiling insulation in attics. In crawlspace applications, it should be at least 4 in above the ground and 1 in below the floor insulation.

Figure 46-53 Properly supported ductboard duct.

Takeoffs

The most common use of ductboard is for plenums and trunk lines in systems that use flex duct for branch ducts. Takeoffs designed specifically for fiberduct should be used. Two types are available: spin-in collars and dovetail collars. The preferable method of cutting the hole is to use a hole cutter that is the same diameter as the collar. If using a spin-in, cut a 1-in slot on the outside of the hole. Cut a ring from a piece of ductboard to insulate the collar. Its inside diameter should be the same as the diameter of the sheet-metal collar. The width of the ring should correspond to the R value of the flexible duct insulation: 1 in wide for R-4, 1.5 in wide for R-6, and 2 in wide for R-8. Slide the ring over the collar and tape it to the collar. Apply mastic to the back of the collar flange and insert the collar into the hole until the flange seats against the face of the ductboard. For spin-ins, this is done by turning the collar clockwise and “threading” it into the hole. Dovetail collars will also go in more easily if they are turned while inserting them. Reach through the collar and bend the tabs on the dovetail over. The flex duct is connected to the takeoff, as described in Section 46.11.

46.11 FLEX DUCT

Both the UL 181 standard and the NFPA 90 standard differentiate between flexible air duct and flexible air connectors. A flexible air duct must pass all fifteen of the UL 181 tests, while air connectors are not required to pass the flame penetration, puncture, or impact tests in standard UL 181. Ducts meeting the more stringent air duct classification can be used in any length, while air connectors are limited to 14 ft. Air connectors are limited to temperature less than 250°F, are not allowed to pass through floors, and are not allowed to pass through walls that are required to have a fire rating.

The markings on the duct indicate whether it is rated as a flexible duct or a flexible connector. Flexible ducts have a square or rectangular label (Figure 46-54), while flexible connectors have a circular label (Figure 46-55). These markings should appear every 10 ft on the duct. Flexible duct is avail-

Figure 46-54 UL 181 flexible duct has a square or rectangle label and has no length restrictions.

Figure 46-55 UL 181 flexible air connector has a round label and cannot be used for lengths over 14 ft.

able in insulation R values of 4.2, 6.0, and 8.0. Many codes require a minimum R value of 6.

Flexible duct is the easiest ducting to install. Unfortunately, it is also the easiest to install incorrectly. Poor craftsmanship not only makes the job unprofessional, but it hurts the airflow as well. Flex duct that is kinked, flattened, or draped in lazy loops will not work correctly (Figure 46-56). The four basic requirements for correctly installing flex duct are as follows:

- Connecting flex duct correctly to takeoffs and fittings
- Stretching the duct to eliminate droops, sags, and crimps
- Trimming the duct to the correct length
- Supporting the duct every 5 ft with 2-in-wide material

Figure 46-56 Incorrectly installed flexible duct system.

Figure 46-57 The inner core is slid over the bead of the fitting and strapped.

Connecting Flex Duct

The basic method of connecting flex duct is to slide the inner core at least 2 in over a metal beaded connector, roll back the outer insulation, fasten the inner core, and then roll the insulation back in place and fasten it. Two approved methods are used for fastening the core and insulation: using UL 181B duct tape or UL 181B mastic and straps.

When using duct tape, the inner core should be taped using at least two wraps of tape. Remember to leave enough metal exposed for the tape to grab. Slide the insulation back in place and tape the insulation in place with at least two wraps of tape.

When using mastic and clamps, UL 181B mastic must be applied to the metal connector before sliding the inner core on. Slide the inner core on past the bead and secure with a strap (Figure 46-57). Roll the insulation in place and secure it with a second strap (Figure 46-58). When the duct is installed vertically, three screws should be run into the metal behind the strap to avoid slipping.

Figure 46-58 The insulation and outer jacket are pulled over the inner core and strapped.

Stretching Flex Duct

Flex duct by its very nature does not want to stay straight. It is necessary to pull it straight to eliminate sags. The maximum allowable sag between supports is 0.5 in/ft.

Trimming Flex Duct

Flex duct should be trimmed to the length needed and no more. Sloppy installers sometimes leave an extra foot or two on the run, knowing they cannot reuse that foot of duct. But leaving extra duct leads to sags, bends, and crimps that severely reduce airflow. Figure 46-59 shows the effect of leaving extra duct length. Figure 46-60 shows a duct that has been trimmed to the correct length.

Supporting Flex Duct

Flex duct is not heavy, but it needs more support than metal duct because it has no structural strength of its own. Flex

Figure 46-59 This run will have a high resistance to airflow.

Figure 46-60 This flexible duct is properly applied; it is tight, straight, and well supported by wide supports.

Figure 46-61 This flex duct is being pinched by the wire that is supporting it.

duct should be supported every 5 ft with straps or hooks that are at least 2 in wide. Galvanized wire and plumbing strap are definitely not appropriate for supporting flex duct. Figure 46-61 shows what happens when flex is supported by wire. Figure 46-62 shows a common abuse of flexible duct: squeezing and twisting it to fit through places that are simply not large enough for the duct. Figure 46-60 shows a properly supported flex run.

46.12 DUCT SEALING

The largest loss of efficiency in a ducted air system comes from air leaks. Unconditioned air leaking into the return-air side of the system can add a considerable heat load. Sealing duct leaks is the fastest way to improve the efficiency of a ducted heating and cooling system. Older homes that have poorly sealed duct systems typically lose 25 percent or more of their system capacity due to duct leaks. Sealing the duct system during installation is relatively simple and does not take a lot of extra time or money. The money spent sealing the system will be recovered during the first year of operation. Figure 46-63 illustrates the effect of sealing and insulating ductwork.

Figure 46-62 Not much air will make it through this duct.

Figure 46-63 Improper duct sealing and poor duct insulation lose a significant portion of a system's capacity and increase utility bills. (Courtesy of Office of Energy Efficiency and Renewable Energy, U.S. Department of Energy)

Sheet-metal ductwork is most commonly sealed with mastic. Mastic has a consistency similar to sheetrock mud and is spread or "painted" on (Figure 46-64). It is stiff but still somewhat flexible after it dries. All duct sealants should be UL-181 approved. Duct tape was once the primary method

Figure 46-64 Applying mastic to sheet metal duct joints.

of sealing metal duct, but tape use is less common today. If duct tape is used, it should be UL-181 approved. There is an abundance of inexpensive duct tape available that is not UL 181 approved, but it should not be used for sealing ductwork.

The biggest leak source in many older systems is found when building cavities are used for return air. It is virtually impossible to seal these properly, resulting in large amounts of attic or crawlspace air being drawn into the system. The best way to correct this is to avoid using building cavities for duct.

Besides building cavities, the largest sources of leaks are around plenums and takeoffs. The holes are frequently not cut precisely, and many times the only attempted seal is duct tape. Close to half the duct leakage in many systems is at the supply and return plenums.

The use of garden-variety duct tape with no mastic is the next most often encountered problem. This type of tape is handy for many things, but sealing ductwork is not one of them. Any connecting and sealing products, including duct tape, should be UL 181 rated. Duct tape that has not passed the UL 181 tests will dry up and harden with age, losing its tackiness and sealing ability. Even the best duct tape is not a particularly effective solution for sealing around plenums and takeoffs; a UL 181 rated mastic is required. Mastic will work fine by itself on small cracks, but tape and mastic will be needed for larger cracks.

Fiberglass ductboard is sealed with UL-181 aluminum foil tape. It is critical to use tape approved by the ductboard manufacturer and apply it according to the manufacturer's instructions. Some of this tape requires heating with an iron to set it. Flexible duct is sealed with both UL-181 tape and mastic. Flexible duct only requires sealing at the ends where it is connected.

TECH TIP

The UL 181A standard covers closure systems for rigid ducts, while the UL 181B standard covers closure systems for flexible ducts and air connectors. Mastics, tapes, and sealants should meet either the UL 181A or the UL 181B standard, depending upon the type of duct.

46.13 TESTING THE DUCTWORK

CODE TIP

The 2009 International Energy Conservation Code (IECC) includes mandatory duct pressure testing coupled with maximum allowable duct leakage rates. These requirements are applicable when any portion of the ducts are outside the conditioned space.

Best-practice duct installation includes testing the duct system for leaks. The most common method is to use a duct blaster (Figure 46-65). All duct outlets are sealed, and a

Figure 46-65 A duct blaster is used to pressurize ducts to find leaks and verify duct system integrity. (Photo provided by The Energy Conservatory)

duct blaster is used to pressurize the entire duct system to 25–50 pascals (0.1–0.2 in wc). After the initial duct pressurization, the amount of airflow required to maintain the pressure is measured. For a completely tight duct system, the airflow would be 0 CFM. However, no system is that tight. The amount of air flowing is the amount leaking out of the ductwork. The amount of acceptable duct leakage depends upon several factors, including the size of the conditioned area the duct system serves and the total amount of airflow through the duct system.

Three methods of quantifying duct leakage are used: percentage of design flow, airflow per 100 ft² of conditioned area, and leakage area. The percent of design flow states the measured leak rate as a percentage of the design flow rate. For example, a system designed to move 1,000 CFM that has a measured leak rate of 100 CFM has a 10 percent leak rate (100 CFM/1,000 CFM = 10 percent). Airflow per 100 ft² of conditioned area calculates the leak rate per 100 ft² of conditioned area and compares it to a maximum acceptable leak rate. For example, a 1,500 ft² house with a system that is leaking 90 CFM has a leak rate of 6 CFM per 100 ft² (1,500/100 = 15, 90/15 = 6). Duct leakage area specifies the size of the hole that would let out the measured CFM if all the combined leakage were combined into a single hole. This area is calculated using a formula that includes the duct pressure and the CFM airflow leak rate.

Energy codes and testing standards vary in what is considered acceptable. When using percent of airflow, less than 6 percent is generally considered good, while anything over 15 percent is generally considered poor. When using CFM per 100 ft², 6 CFM at rough-in or 8 CFM after construction is often considered the maximum acceptable leakage rate.

TECH TIP

Testing the duct leakage before insulating it will save time by avoiding the removal of insulation to get at the points that need sealing.

46.14 INSULATING DUCTWORK

Fiberglass ductboard does not need to be insulated because it is made of fiberglass and has inherent thermal insulating properties. Flexible duct does not need to be insulated either, because fiberglass insulation is part of its construction. Sheet-metal ducts do need to be insulated. Sheet-metal ductwork can be insulated on the inside with duct liner or on the outside with duct wrap.

Duct liner is applied to the inside of the duct. It is available in thicknesses from $\frac{1}{2}$ in to 2 in. In general, duct liner is made of a denser fiberglass material than duct wrap. Duct liner reduces the interior size of the ductwork, so the ducts must be made with larger dimensions to accommodate the use of duct liner.

The most common duct wrap is fiberglass with an outer vapor barrier. It is commonly available in 1.5-in and 2-in thicknesses. Many energy-efficiency codes now require the 2-in-thick duct wrap. The vapor barrier prevents condensation on the outside of the duct during air conditioning when the duct temperature may be below the dew-point temperature of the area the duct is in. Condensation on the duct represents a significant loss of system efficiency and can cause property damage from dripping. The vapor barrier can be vinyl or paper and aluminum foil kraft back.

46.15 DUCT CLEANING

Duct-cleaning standards and duct-cleaning technician certifications are established by the National Air Duct Cleaners Association. A key point in discussing duct cleaning is that typically the entire system needs cleaning, not just the ducts. Blowers, coils, and filters should all be checked and cleaned whenever ductwork is cleaned. System components, including ducts, accumulate a fine layer of dust over time. In most systems there is more dust accumulation in the return than the supply. Mold can also sometimes grow in ductwork, but the presence of mold indicates a more serious problem than simply dirty ducts. The mold can be cleaned, but if the root cause is not addressed, the mold will return. Mold requires moisture to live; if mold is growing in the system, moisture is getting in. Finding and eliminating the source of moisture is necessary for long-term mold remediation.

A visual inspection is necessary to determine the need for cleaning. A visual inspection after cleaning is necessary to assess the results. Duct systems should have inspection ports at major turns and after any obstruction, such as coils or filters. Frequently these will have to be added the first time a system is cleaned. Tools are available that enable inspection of the duct system via remote video cameras

Figure 46-66 Video inspection tool for examining the inside of ductwork before and after cleaning. (Courtesy of Abatement Technologies, Inc.)

(Figure 46-66). This enables the technician to see what must be cleaned, even if the area is around a corner. Video inspection systems also allow the customer to see the results of the job.

Most duct-cleaning equipment is some form of specialized vacuum cleaner. Some systems are large units mounted on the back of a truck with large hoses connected to the ducts in the house. These systems move a large volume of air and rely on this air volume and velocity to remove debris from the duct. Other systems are much smaller and use a series of brushes along with inspection tools. Some systems use a percussive tool that flails around inside the duct to knock dirt loose. These systems will only work with metal ducts.

Metal ducts are the easiest to clean because they are not likely to be damaged by the cleaning equipment. Fiberglass duct and fiberglass-lined duct can be cleaned with soft-bristle brushes, but heavy agitation or stiff brushes can damage the fiberglass and do more harm than good. Flex duct can sometimes be cleaned with gentle brushes, but it may be more practical to replace it than clean it. Fabric duct systems (Figure 46-67) can literally be taken down and washed.

UNIT 46—SUMMARY

A properly designed and installed duct system:

- Allows for proper airflow through the system
- Delivers conditioned air throughout the structure according to the heat load
- Does not leak
- Is well insulated and thermally efficient
- Is quiet

This can be achieved using sheet metal, ductboard, flex duct, or any combination of these materials. The difference between a poor duct system and a good one is often just a matter of a few minutes and a little extra material. Sealing metal ducts, trimming flex ducts, or fabricating fiberglass ducts are not complicated tasks; they just take a little extra time and material.

WORK ORDERS

Service Ticket 4601

Job: Duct Tightening

Equipment Type: 20-Year-Old Split-System Air Conditioner with All Metal Duct

A customer contracted for a duct tightening job because the local electric utility has a rebate for duct tightening. The contractor is required to reduce the duct leakage by at least 50 percent. The technician starts by measuring the duct leakage with a duct blaster. Next, the old outer insulation around the plenum is removed. Many leaks are evident around both the supply and return plenums. The technician uses UL 181A tape and mastic to seal these leaks and retests the system and finds that simply sealing the leaks around the plenums reduced the duct leakage by 30 percent. The technician goes on to check the rest of the system and wraps the plenum with new higher-R-value insulation.

Service Ticket 4602

Complaint: Poor Airflow in Office

Equipment Type: Commercial System Using a Metal Trunk and Flex Duct Drops

The vice president of customer assurance at APEX Industries moves into a newly renovated office and finds it stuffy. There is very little air coming out of the ceiling register. The technician who is called to fix the problem looks above the ceiling and notices that the flex run is too long and is almost doubled over. The flex is trimmed to an appropriate length and stretched so that the air has a straight shot. The register now has adequate airflow.

Service Ticket 4603

Complaint: Musty Odor When Unit Runs

Equipment Type: Split System in Crawlspace with Ductboard Trunk Line and Flex Runouts

A technician is called to look at a system that is blowing musty air into the house and notices that the fiberduct plenums are only attached to the 0.5-in flanges on the unit with duct tape. They are both leaky, but the return plenum has sagged and there is a gap on one side between the plenum and the unit. The technician also notices that there is no vapor barrier on the ground. The plenums are removed, 2-in-wide sheet metal flanges are connected to the unit's 0.5-in flanges with sheet metal screws, and the plenums are reattached using three long sheet-metal screws with large washers on each side of the plenums to attach them to the new metal flanges. The plenums are then sealed to the unit with UL 181A duct tape. The technician recommends that the customer install a vapor barrier over the exposed dirt in the crawlspace.

Service Ticket 4604

Job: Duct Cleaning

Equipment Type: Metal Trunk Line and Runouts

A customer notices that the ductwork by his filter grille is very dirty on the inside and calls to have his ducts cleaned. The technician uses the video inspection tool to see the extent of the dirt, makes a tape of the inspection, and shows the customer. The ducts are cleaned using a portable duct-cleaning machine with soft bristles on the trunk lines. The blower wheel and evaporator coil are also cleaned. The technician makes a new tape showing the ducts after cleaning and suggests that the customer consider installing a high-efficiency air cleaner to keep the ducts clean.

Service Ticket 4605**Complaint: No Airflow in Bedroom****Equipment Type: Radial System with Lined Metal Plenum with Flex Runouts**

A new system has no airflow in the master bedroom. The technician looks at the duct run to the bedroom and sees no obvious problems. After removing the flex duct from the plenum, the technician finds that the liner in the plenum was not entirely cut out. After cutting out the liner and reattaching the duct, the bedroom has good airflow.

UNIT 46—REVIEW QUESTIONS

1. What standard covers ductboard and methods of connecting and sealing ductboard?
2. What standard covers flexible duct and methods of connecting and sealing flexible duct?
3. What is the difference between Class 0 duct and Class 1 duct?
4. List the agencies that promote duct standards, and briefly describe what they cover.
5. Explain the difference between a flexible duct and a flexible air connector.
6. List the materials commonly used to construct duct systems.
7. Describe how two pieces of round sheet-metal pipe are joined.
8. Describe how sheet-metal ductwork is sealed.
9. Describe how to join fiberboard duct.
10. How far apart should hangers for metal duct be placed?
11. How far apart should hangers for fiber ductboard be placed?
12. Describe the proper method of hanging flexible duct.
13. List four methods of insulating metal ductwork.
14. Using Table 58-2, what width should 2-in fiberglass duct insulation be to wrap an 8-in-diameter round duct?
15. Describe how ductboard is formed into ducts.
16. List three types of takeoff fittings available for sheet-metal duct.
17. Describe how to install a dovetail takeoff fitting on a ductboard trunk.
18. What are some of the limitations on the use of flexible air connectors?
19. Describe how rectangular sheet-metal ducts are joined.
20. How do the staples that hold duct insulation together work?
21. What is the correct spacing for the mechanical fasteners used to hold duct liner in place?
22. Discuss some of the major problems that cause leaky duct systems in older homes.
23. How does a duct blaster measure the amount of duct leakage?
24. What are the two main types of duct-cleaning equipment being used?
25. Why is a visual inspection necessary when cleaning ductwork?
26. What are the three methods used to quantify duct leakage?

UNIT 47

Troubleshooting Air-Conditioning Systems

OBJECTIVES

After completing this unit, you will be able to:

1. troubleshoot air-conditioning system air-distribution problems.
2. adjust air-conditioning system airflow.
3. troubleshoot air-conditioning system electrical problems.
4. perform diagnostic tests on air-conditioning system electronic controls.
5. read and interpret troubleshooting charts.
6. troubleshoot air-conditioning system mechanical problems.

47.1 INTRODUCTION

Troubleshooting an air-conditioning system correctly will result in the proper repair for the unit in a timely fashion. It is discouraging for the customer and the technician if multiple return visits are required to correct a malfunctioning unit. The trouble described by the customer may initially help you to determine which course of action needs to be taken. It will save you time to take a few minutes to discuss the symptoms with them. They may be able to provide you with valuable information that may lead you to the problem.

Most manufacturers supply troubleshooting charts for their equipment. After speaking with the customer, a good next step is to review these to assist in troubleshooting the system. A quick simple fix may not always be the correct answer. For example, the unit may be tripped out due to a stuck high-water-level switch on the evaporator condensate drip pan, as shown in Figure 47-1.

Simply resetting the unit may bring it back on line, but if it trips out again you will be called to come back to the residence a second time. Before leaving the job, the drain pipe should be checked for an obstruction.

Figure 47-1 Float switch on condensate tray. (Courtesy of InspectAPedia.com)

Figure 47-2 Refrigerant-charging service data tag. (Courtesy of InspectAPedia.com)

To avoid these types of situations, it is best to take the proper steps in evaluating the malfunction. Collect information about the problem. Read and calculate the system's vital signs, such as suction and discharge pressures. Compare the measured values to the expected manufacturer's recommendations (Figure 47-2). Consult the manufacturer's troubleshooting aids, if available, along with any company-specific troubleshooting guides.

SAFETY TIP

Electrical testing is generally a first step in any troubleshooting sequence. Make sure that you properly identify the power supply to the unit (Figure 47-3). Do not assume that the power is always shut off at the breaker. Sometimes breakers are mislabeled. Always use your meter to check for ground faults before energizing the unit to be serviced. At all times, use your meter to check for voltage before physically disconnecting wires or opening control boxes.

Figure 47-3 Service control switch circuit breaker.

47.2 SYSTEM FAMILIARIZATION

The air-conditioning system design may affect the way you troubleshoot the system. It is important to familiarize yourself with the system components and their location. Is the evaporator coil located in an indoor air-handling unit or is it installed in conjunction with a furnace? Is the air handler a vertical upflow, vertical downflow, or horizontal unit, and where is it located? Where are the system controls and switches located? What type of safety controls does the unit have? Check the capacity ratings for the system (Figure 47-4). A split system has a fan coil unit with a refrigeration coil located on the inside of the building and an outside-mounted air-cooled condensing unit, connected together with refrigerant piping. A typical split system with an air-handling unit in the ceiling is shown in Figures 47-5 and 47-6.

Basically, there are three types of problems: trouble with the air system, the electrical system, or mechanical components. Within these there is much overlap, so whatever the nature of the problem, it is good practice to follow a logical, structured, systematic approach. In this manner, the correct solution is usually found in the shortest possible time.

47.3 AIR SYSTEM PROBLEMS

The primary problem that can occur in an air system is the reduction in airflow. Air-handling systems do not suddenly increase in capacity—that is, increase the amount of air

Figure 47-4 Split-system data tag. (Courtesy of InspectAPedia.com)

across the coil. On the other hand, the refrigeration system does not suddenly increase in heat-transfer ability. First remove the panel to access the direct expansion (DX) coil in the air handler (Figure 47-7) so that you can inspect the coil for dirt and blockage. On many systems, removing a panel would change the airflow across the coil and change the return and supply reading. Take the temperatures of the return air as it enters and then the supply air as it leaves the coil. The difference between these two temperatures is referred to as the temperature drop or temperature difference of the air across the DX coil.

A sling psychrometer is used to measure the return-air dry-bulb and wet-bulb temperatures needed to determine the relative humidity. Many electronic psychrometers are able to display relative humidity directly. A chart as shown in Figure 47-8 or one supplied by the DX coil manufacturer is then used to determine the expected temperature drop. As an example from the chart, return air at a condition of 68°F and 30 percent relative humidity should have a 24°F air temperature drop across the coil.

This measurement will help to determine if the problem is a result of improper airflow or a refrigeration system error. If the actual air temperature drop is greater than the required temperature drop, then the air quantity has been reduced. In this case, look for problems in the air-handling system. This could be due to dirty air filters, a dirty evaporator coil, a problem with the blower, or an unusual restriction in the duct system.

Air Filters

Because this is the most common problem of air failure, check the filtering system first (Figure 47-9). Air filters of the throwaway type should be replaced at least once a month.

Blower Motor and Drive

Check the blower motor and drive in the case of belt-driven blowers to make sure that both the blower motor and blower bearing are properly lubricated and operating freely. The blower drive belt must be in good condition and properly adjusted. Cracked or heavily glazed belts must be replaced. Heavy glazing can be caused by too much tension on the belt, driving the belt down into the pulleys. Proper

Figure 47-5 Ceiling evaporator blower installation.

Figure 47-6 Attic-mounted air handler. (Courtesy of InspectAPedia.com)

Figure 47-7 Air-handler unit and coil. (Courtesy of InspectAPedia.com)

Figure 47-8 Air-temperature drop for various return-air conditions.

Figure 47-9 Dirty air filter (Courtesy of InspectAPedia.com)

adjustment requires the ability to depress the belt midway between the pulleys approximately 1 in for each 12 in between pulley centers.

The blower wheel should be clean. Dirt accumulation can sometimes fill in the area on a cupped blade, allowing it to spin freely but substantially reducing the airflow (Figure 47-10). If the wheel is dirty or has mold buildup (Figure 47-11), it must be removed and cleaned. Attempting to clean the wheel in place is never recommended. Do not try brushing only, because a poor cleaning job will cause an imbalance to occur on the wheel. Extreme vibration and noise will result. This could cause deterioration of the wheel, damage to the belt, and damage to the motor.

Figure 47-10 Dirty blower fan. (Courtesy of InspectAPedia.com)

Figure 47-11 Mold growth on blower fan. (Courtesy of InspectAPedia.com)

Unusual Restrictions in Duct Systems

Placing furniture or carpeting over return grilles reduces the air available for the blower to handle (Figure 47-12). Shutting off the air to unused areas will reduce the air over the coil. Covering a return-air grille to reduce the noise from the centrally located furnace or air handler may reduce the objectionable noise, but it also drastically affects the operation of the system by reducing air quantity.

The condition of the grille may also indicate potential problems. Water stains (Figure 47-13) can be caused by improper humidity conditions. Soot stains (Figure 47-14) may be a result of an improperly functioning furnace's exhaust leaking back into the air-supply line.

The collapse of the return-air duct system will affect the entire duct system performance (Figure 47-15). Air leaks in the return duct will raise the return-air temperature and reduce the temperature drop across the coil (Figure 47-16). Look for pinched ducts (Figure 47-17), sharp bends (Figure 47-18), and unnecessary duct length (Figure 47-19).

Figure 47-18 Duct sharp bend. (Courtesy of InspectAPedia.com)

Figure 47-19 Unnecessary duct length. (Courtesy of InspectAPedia.com)

Figure 47-20 Checking return-air system for leaks.

TECH TIP

Air-distribution systems installed before the change in standards may have cloth or unapproved duct tape. These systems may need to be sealed properly for the central residential air-conditioning system to function properly. The technician should give particular attention to the integrity of the sealing of all joints and the insulation and tape if externally wrapped.

Measure the difference in temperature between the return air at the grille compared to the return-air temperature as it enters the unit. This difference should not exceed 2°F (Figure 47-20). If it does, the return duct needs to be insulated or there may be leak openings in the duct that need to be sealed.

SAFETY TIP

Some older fabric air-handler vibration dampers are made from asbestos (Figure 47-21). Always follow the proper procedures for handling asbestos materials. Never rip or tear the asbestos, and always wear an approved respirator.

Condensate Drain Pans

Condensate drain pans are located below the DX coil to collect any moisture that condenses from the air and drips off the coil. Depending on the humidity conditions, the amount

(a)

(b)

Figure 47-21 (a) Asbestos fabric in HVACR duct as vibration-damper material; (b) asbestos fabric air-handler vibration damper. (Courtesy of InspectAPedia.com)

of water drained away can be considerable. The condensate that collects will build up and overflow the pan if the drain becomes plugged or offers restricted flow. This is of particular concern with attic-mounted units because the condensate will spill over and damage the ceiling. Some condensate drip pans have condensate pumps that will stop and start automatically and are controlled by a float switch activated by the water level. Even if the condensate drain pan is empty, any signs of prior spillover should be investigated further.

Adjusting the Airflow

Most manufacturers supply operating data on their equipment (Table 47-1), indicating the total, sensible, and latent heat-removal rating at various outdoor dry-bulb and indoor wet-bulb temperatures at specific static pressures. For these same conditions, they supply the operating suction and discharge pressures of the equipment. This information is given so that the technician can match the actual condi-

tions on the job with the performance conditions shown on the manufacturer's chart. Notice that in Table 47-2 a system with a low external static pressure of 0.30 would have an airflow of 625 CFM on LOW. But on a system with a higher external static pressure of 0.70, the blower would have to be set to HIGH to obtain the same airflow.

SERVICE TIP

Most manufacturers recommend that a system's airflow be set so there is approximately 400 CFM per ton of air conditioning. In areas that have high relative humidity, a slightly slower fan speed can be used to aid in the dehumidification. In arid areas, the fan speed can be increased to provide more sensible cooling. As a rule of thumb, the fan speed should not be adjusted more than 10 percent above or below the manufacturer's recommendations. Excessively slow fan speeds can allow the evaporator coil to freeze up under light loads, and excessively high fan speeds can put too large a load on the condenser under heavy load conditions.

47.4 ELECTRICAL PROBLEMS

Since the greatest numbers of malfunction problems are electrical, it is common practice to perform electrical troubleshooting (including controls) before mechanical troubleshooting. If the problem is mechanical, the electrical check will usually point the technician in that direction. If the system will not operate at all, it is probably an electrical problem that must be found and corrected.

TECH TIP

Before beginning any troubleshooting, you must locate the manufacturer's troubleshooting guide for the equipment you are working on (Table 47-3). Manufacturers have developed troubleshooting techniques that when followed will result in accurate and rapid location of the problem. These charts may seem complex and difficult to follow if you look at the entire chart, so to properly use one of these charts, start at the beginning and follow each and every step. Do not simply jump ahead assuming that you know what the answer is. Do the test and report the results, and then move to the next test as indicated by the manufacturer's guide.

Electrical Operating Sequence

The operating sequence is usually supplied by the manufacturer in the service instructions, or it can be determined by the technician by studying the schematic wiring diagram. The functions of the operating and nonoperating equipment are determined by examination and testing. Necessary test

Note: All air data are measured external to unit with air filter in place. Electric heaters have no appreciable air resistance.

instruments include the volt ohm meter, the clamp-on ammeter, the capacitor tester, and the temperature analyzer. The power circuit is the first to be examined, because power must be available to operate the loads. For example, on a refrigeration system with an air-cooled condenser, the three principal loads that must be energized are the compressor motor, the condenser fan motor, and the evaporator fan motor. Before proceeding with anything else, the technician must be certain that the proper voltage is being supplied to the loads. The supply-line voltage should be tested with a voltmeter and then compared to the manufacturer's recommended values.

If the voltage is correct, then the circuit will need to be tested further. Before energizing the circuit, always use your meter to check for ground faults. Once energized, the voltage for each load in the circuit can be tested. A clamp-on ammeter can be used to check the current draw for each load one at a time. The measured current should be compared to the current rating listed on the motor nameplate. As an example, if the current draw is too high, this may indicate a mechanical problem such as a stuck fan or seized compressor.

In troubleshooting, when a load is not working, the technician must determine whether the problem is in the load itself or in the switches that control the load. If the proper supply voltage is available but the compressor or fan motor does not run, then there may be a fault in the control circuit and the control circuit voltage should be tested. Generally the control circuit voltage will be much lower than the line voltage. Each load, compressor, or fan is generally controlled by a relay switch operated by an electromagnetic coil energized by the control circuit.

Use your meter to check for voltage before physically disconnecting wires or opening control boxes. Always test to determine if the fan or motor is tripped out on a safety switch before replacing components. When checking components with an ohmmeter, it is important that all power is disconnected and the component part is electrically isolated. Short circuits are usually due to faulty loads. If a faulty component is located, the job is still not complete. The technician should make a concerted effort to determine why or how the component failure occurred.

Installation and Service Instructions

The installation and service instructions supply a wide variety of information that the manufacturer believes is necessary to properly install and service the unit. This bulletin includes the wiring diagram, the sequence of operation, and any notes or cautions that need to be observed in using them.

Wiring Diagrams

Wiring diagrams usually consist of connection diagrams and schematic diagrams. The connection diagram shows the wires to the various electrical component terminals in their approximate location on the unit. This is the diagram that the technician must use to locate the test points. The schematic diagram separates each circuit to clearly indicate the function of switches that control each load. This is the diagram the technician uses to determine the sequence of operation for the system.

TABLE 47-3 Troubleshooting Chart: Cooling Service

Problem	Cause	Remedy
Compressor and condenser fans will not start.	Power failure Fuse blown or circuit breaker tripped Defective thermostat, contactor, transformer, or control relay Insufficient line voltage Incorrect or faulty wiring Thermostat setting too high	Call power company. Replace fuse or reset circuit breaker. Replace component. Determine cause and correct. Check wiring diagram and rewire correctly. Lower thermostat setting below room temperature. Check wiring and repair or replace.
Compressor will not start but condenser fans run.	Faulty wiring or loose connections in compressor circuit Compressor motor burned out, seized, or internal overload open Defective run/start capacitor, overload, or start relay One leg of three-phase power dead	Determine cause. Replace compressor. Determine cause and replace. Replace fuse or reset circuit breaker.
Compressor cycles (other than normally satisfying thermostat).	Refrigerant overcharge or undercharge Defective compressor Insufficient line voltage Blocked condenser Defective run/start capacitor, overload, or start relay Defective thermostat Faulty condenser-fan motor or capacitor Restriction in refrigerant system Compressor rotating in wrong direction	Recover refrigerant, evacuate system, and recharge to nameplate. Replace and determine cause. Determine cause and correct. Determine cause and correct. Determine cause and replace. Replace thermostat. Replace. Locate restriction and remove. Reverse the three-phase power leads.
Compressor (scroll only) makes excessive noise.		
Compressor operates continuously.	Dirty air filter Unit undersized for load Thermostat set too low Low refrigerant charge Leaking valve in compressor Air in system Condenser coil dirty or restricted	Replace filter. Decrease load or increase unit size. Reset thermostat. Locate leak, repair, and recharge. Replace compressor. Recover refrigerant, evacuate system, and recharge. Clean coil, remove restriction.
Head pressure too high.	Dirty air filter Dirty condenser coil Refrigerant overcharged Air in system Condenser air restricted or air short-cycling	Replace filter. Clean coil. Remove excess refrigerant. Recover refrigerant, evacuate system, and recharge. Determine cause and correct.
Head pressure too low.	Low refrigerant charge Compressor valves leaking Restriction in liquid tube	Check for leaks, repair, and recharge. Replace compressor. Remove restriction.
Suction pressure too high.	High heat load Compressor valves leaking Refrigerant overcharged	Check for source and eliminate. Replace compressor. Recover excess refrigerant.
Suction pressure too low.	Dirty air filter Low refrigerant charge Metering device or low side restricted Insufficient evaporator airflow Temperature too low in conditioned area Field-installed filter drier restricted Unit in economizer mode	Replace filter. Check for leaks, repair, and recharge. Remove restriction. Increase air quantity. Check filter and replace as necessary. Reset thermostat. Replace. Proper operation; no remedy necessary.
Compressor no. 2 will not run.		

TECH TIP

Wiring diagrams are often included inside the equipment panels. If the diagrams are not there, then contact the manufacturer. They are available from local suppliers and are often available from the manufacturers themselves through their Web sites. If you do not have a diagram, troubleshooting electrical circuits can be lengthy, time-consuming, and inaccurate.

Troubleshooting Tables

Troubleshooting tables are helpful as a guide to corrective action. By a process of elimination, such tables offer a quick way to solve a service problem. The process of elimination permits the technician to examine each suggested remedy and disregard ones that do not apply or are impractical; leaving only the solution(s) that fits the problem.

Fault Isolation Diagrams

A fault isolation diagram (Figure 47-22) starts with a failure symptom and goes through a logical decision action process to isolate the failure.

Diagnostic Tests

Diagnostic tests can be conducted on electronic circuit boards, at points indicated by the manufacturer, to check voltages or other essential information critical to the operation of the unit.

Some electronically controlled systems have automatic testing features, which indicate by code number a malfunction in the operation of the equipment (Figure 47-23). Further tests are usually required to determine the action that is required.

47.5 MECHANICAL PROBLEMS

When the measured temperature drop across the DX coil is less than required, this means that the heat-removal capacity of the system has been reduced. This means that the amount of heat picked up in the coil plus the amount of motor heat added and the total rejected from the condenser is not the total heat quantity the unit is designed to handle. The problems associated with a system that starts and runs but does not produce satisfactory cooling can be simply divided into two categories: refrigerant quantity and refrigerant flow rate.

To determine the problem, all the information listed in Table 47-4 must be measured. These results compared to normal operating results will generally identify the problem. The use of the word *normal* does not imply a fixed set of pressures and temperatures. These will vary with each make and model of the system. A few temperatures are fairly consistent throughout the industry and can be used for comparison. These are the DX coil operating tempera-

ture, the condensing unit condensing temperature, and the refrigerant subcooling.

SERVICE TIP

These vital signs must also be modified according to the seasonal energy efficiency ratio (SEER) of the unit. The reason for this is that the amount of evaporation and condensing surface designed into the unit is directly related to the efficiency rating. A larger condensing surface results in a lower condensing temperature and a higher SEER. A larger evaporating surface results in a higher suction pressure and a higher SEER. The energy efficiency ratio is calculated by dividing the net capacity of the unit in BTU/hr by the watts input. Every central split cooling system manufactured in the United States today must have a SEER of at least 13.

47.6 DX COIL OPERATING TEMPERATURE

Normal coil operating temperatures can be found by subtracting the design DX coil split from the average air temperature going through the coil. The DX coil split will vary with the system design. The term *coil split* is also often referred to as the temperature split or the approach temperature. It is the difference in temperature between the coil (condenser or evaporator) and the air passing across it.

The energy efficiency ratio (EER) is the output in BTU/hr divided by the power input measured in watts. It is less meaningful than SEER because it is a steady state rating and does not account for the time the unit operates before reaching its peak efficiency. However, the EER is still useful in determining coil operating temperatures. Systems in the EER range of 7.0 to 8.0 will have DX coil design splits in the range of 25°F to 30°F. Systems in the EER range of 8.0 to 9.0 will have DX coil design splits in the range of 20°F to 25°F. Systems with 9.0+ EER ratings will have DX coil design splits in the range of 15°F to 20°F.

The normal DX coil operating temperature will be affected by the air passing across it. The air passing across the coil will have an inlet and an outlet temperature. The inlet air is the return air and can also be referred to as the entering air temperature (EAT). The outlet air is the supply air and can also be referred to as the leaving air temperature (LAT). The EAT – LAT is equal to the temperature difference (TD or ΔT) of the air across the DX coil. The average temperature of the air passing across the coil can be calculated as $TD \div 2$. This calculated average temperature of the air can be used to calculate the normal DX coil operating temperature. The formula used for determining coil operating temperature (COT) is

$$COT = \frac{(EAT + LAT)}{2} - \text{DX coil split}$$

For example, a unit having an entering air condition of 80°F DB and leaving air temperature of 60°F will have an operating coil temperature determined as in the following example.

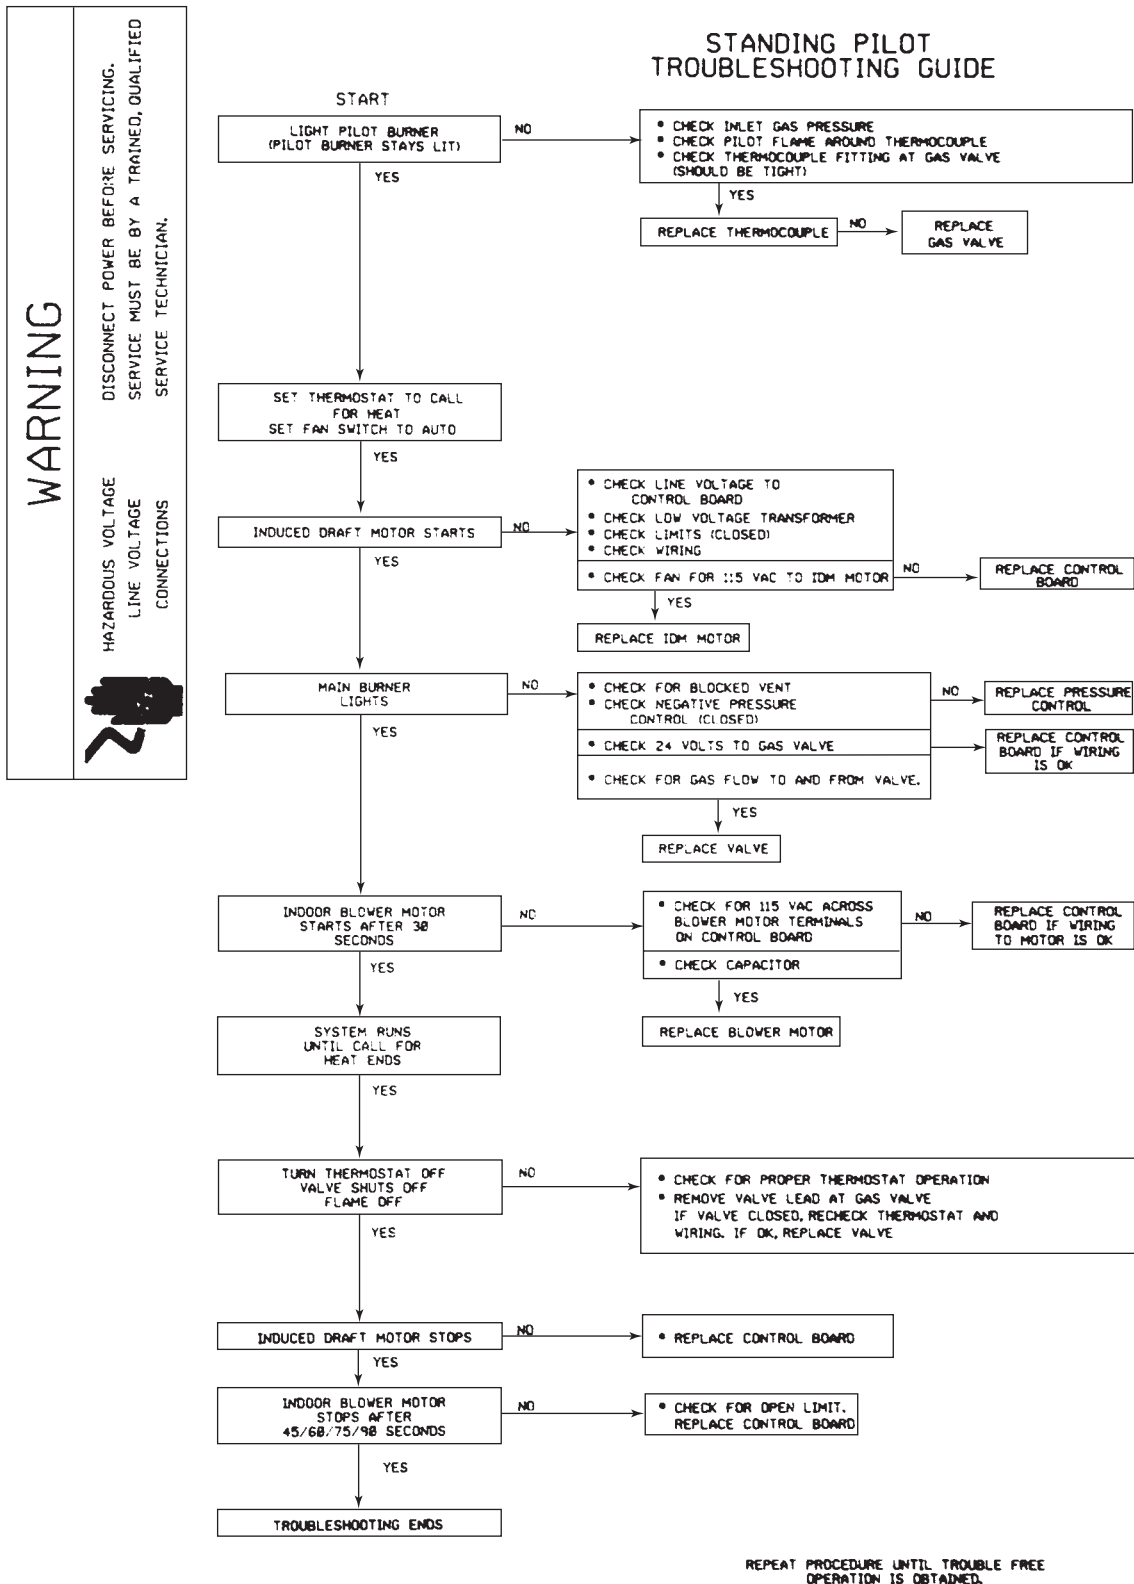

Figure 47-22 Typical fault-isolation diagram.

Figure 47-23 Fault codes.

Fault Codes		
FAULT CODE	FAULT NAME IN PANEL	DESCRIPTION AND RECOMMENDED CORRECTIVE ACTION
1	OVERCURRENT	Output current is excessive. Check for excessive motor load, insufficient acceleration time (parameters 2202 ACCELER TIME 1, default 30 seconds), or faulty motor, motor cables or connections.
2	DC OVERVOLT	Intermediate circuit DC voltage is excessive. Check for static or transient over voltages in the input power supply, insufficient deceleration time (parameters 2203 DECELER TIME 1, default 30 seconds), or undersized brake chopper (if present).
3	DEV OVERTEMP	Drive heat sink is overheated. Temperature is at or above 115 °C (239 °F). Check for fan failure, obstructions in the airflow, dirt or dust coating on the heat sink, excessive ambient temperature, or excessive motor load.
4	SHORT CIRC	Fault current. Check for short-circuit in the motor cable(s) or motor or supply disturbances.
5	OVERLOAD	Inverter overload condition. The drive output current exceeds the ratings.
6	DC UNDERVOLT	Intermediate circuit DC voltage is not sufficient. Check for missing phase in the input power supply, blown fuse, or under voltage on main circuit.
7	AI1 LOSS	Analog input 1 loss. Analog input value is less than AI1 FLT LIMIT (3021). Check source and connection for analog input and parameter settings for AI1 FLT LIMIT (3021) and 3001 AI-MIN FUNCTION.
8	AI2 LOSS	Analog input 2 loss. Analog input value is less than AI2 FLT LIMIT (3022). Check source and connection for analog input and parameter settings for AI2 FLT LIMIT (3022) and 3001 AI-MIN FUNCTION.
9	MOT OVERTEMP	Motor is too hot, as estimated by the drive. Check for overloaded motor. Adjust the parameters used for the estimate (3005 through 3009). Check the temperature sensors and Group 35 parameters.
10	PANEL LOSS	Panel communication is lost and either drive is in local control mode (the control panel displays LOC), or drive is in remote control mode (REM) and is parameterized to accept start/stop, direction or reference from the control panel. To correct, check the communication lines and connections. Check parameter 3002 PANEL COMM ERROR, parameters in Group 10: Command Inputs and Group 11: Reference Select (if drive operation is REM).
11	ID RUN FAIL	The motor ID run was not completed successfully. Check motor connections.
12	MOTOR STALL	Motor or process stall. Motor is operating in the stall region. Check for excessive load or insufficient motor power. Check parameters 3010 through 3012.
13	RESERVED	Not used.
14	EXT FAULT 1	Digital input defined to report first external fault is active. See parameter 3003 EXTERNAL FAULT 1.
15	EXT FAULT 2	Digital input defined to report second external faults is active. See parameter 3004 EXTERNAL FAULT 1.
16	EARTH FAULT	The load on the input power system is out of balance. Check for faults in the motor or motor cable. Verify that motor cable does not exceed maximum specified length.
17	UNDERLOAD	Motor load is lower than expected. Check for disconnected load. Check parameters 3013 UNDERLOAD FUNCTION through 3015 UNDERLOAD CURVE.
18	THERM FAIL	Internal fault. The thermistor measuring the internal temperature of the drive is open or shorted. Contact your Carrier representative.
19	OPEX LINK	Internal fault. A communication-related problem has been detected between the OMIO and OINT boards. Contact your Carrier representative.
20	OPEX PWR	Internal fault. Low voltage condition detected on the OINT board. Contact your Carrier representative.
21	CURR MEAS	Internal fault. Current measurement is out of range. Contact your Carrier representative.
22	SUPPLY PHASE	Ripple voltage in the DC link is too high. Check for missing main phase or blown fuse.
23	RESERVED	Not used.
24	OVERSPEED	Motor speed is greater than 120% of the larger (in magnitude) of 2001 MINIMUM SPEED or 2002 MAXIMUM SPEED parameters. Check parameter settings for 2001 and 2002. Check adequacy of motor braking torque. Check applicability of torque control. Check brake chopper and resistor.
25	RESERVED	Not used.
26	DRIVE ID	Internal fault. Configuration block drive ID is not valid.
27	CONFIG FILE	Internal configuration file has an error. Contact your Carrier representative.

Table 47-4 Troubleshooting Chart for Refrigeration and Air-Conditioning Systems, Showing Symptoms and Probable Causes

Probable Cause	Low-Side (Suction) Pressure (psig)	D.X. Coil Superheat (°F)	High-Side (Hot Gas) Pressure (psig)	Condenser Liquid Subcooling (°F)	Cond. Unit Amperage Draw (A)
1. Insufficient or unbalanced load	Low	Low	Low	Normal	Low
2. Excessive load	High	High	High	Normal	High
3. Low ambient (cond. entering air °F)	Low	High	Low	Normal	Low
4. High ambient (cond. entering air °F)	High	High	High	Normal	High
5. Refrigerant undercharge	Low	High	Low	Low	Low
6. Refrigerant overcharge	High	Low	High	High	High
7. Liquid-line restriction	Low	High	Low	High	Low
8. Plugged capillary tube	Low	High	Low	High	Low
9. Suction-line restriction	Low	High	Low	Normal	Low
10. Hot-gas line restriction	High	High	High	Normal	High
11. Inefficient compressor	High	High	Low	Low	Low

EXAMPLE 47-1: SOLVING FOR DX COIL OPERATING TEMPERATURE

For an EER rating of 7.0 to 8.0, the DX coil split is typically 25–30°F.

$$\text{COT} = \left(\frac{80^\circ\text{F} + 60^\circ\text{F}}{2} \right) - (25 \text{ to } 30^\circ\text{F}) = 40 \text{ to } 45^\circ\text{F}$$

For an EER rating of 8.0 to 9.00, the DX coil split is typically 20–25°F.

$$\text{COT} = \left(\frac{80^\circ\text{F} + 60^\circ\text{F}}{2} \right) - (20 \text{ to } 25^\circ\text{F}) = 45 \text{ to } 50^\circ\text{F}$$

For an EER rating of 9.0+, the DX coil split is typically 15–20°F.

$$\text{COT} = \left(\frac{80^\circ\text{F} + 60^\circ\text{F}}{2} \right) - (15 \text{ to } 20^\circ\text{F}) = 50 \text{ to } 55^\circ\text{F}$$

This demonstrates that the operating coil temperature changes with the EER rating of the unit.

For an EER rating of 9.0+, the condenser split is typically 15 to 20°F:

$$\text{Operating RCT} = 95^\circ\text{F} + (15 \text{ to } 20^\circ\text{F}) = 110 \text{ to } 115^\circ\text{F}$$

This demonstrates that the operating RCT varies not only from changes in outdoor temperatures but with the different EER ratings.

TECH TIP

As an air-conditioning system picks up heat, the temperature and pressure of the system increases on the suction side. If the air-conditioning system cannot pick up heat in the evaporator, the suction pressure and temperature will go down. If the condenser is unable to reject the heat, the condenser temperature and pressure will go up. If the condenser is not receiving heat, its temperature and pressure will go down. Heat and temperature and pressure are all interrelated. If a system has lower than normal pressure and temperature, then heat is not being picked up. This may be caused by low airflow or low refrigerant charge. If a system has higher temperatures and pressures than normal, it is either picking up more heat than can be rejected by the condenser or the condenser is unable to reject the heat normally. The bottom line is that if you follow the temperature and pressure, you will follow the heat, which will enable you to diagnose refrigerant circuit problems.

47.7 CONDENSING UNIT CONDENSING TEMPERATURE

The amount of surface in the condenser affects the condensing temperature the unit must develop to operate at rated capacity. The variation in the size of the condenser also affects the production cost and price of the unit. A smaller condenser will have a lower price, but it will also have a lower EER rating. In the same EER ratings used for the DX coil, at 95°F outside ambient, the 7.0 to 8.0 EER category will operate in the 25 to 30°F condenser split range, the 8.0 to 9.0 EER category in the 20 to 25°F condenser split range, and the 9.0+ EER category in the 15 to 20°F condenser split range.

The condenser split is the design temperature difference between the refrigerant condensing temperature (RCT) and the entering air temperature of the condenser (EAT).

$$\text{Condenser split} = \text{design RCT} - \text{design EAT}$$

To calculate the actual operating refrigerant condensing temperature in the condenser coil, the entering air temperature and the condenser split will be required.

$$\text{Operating RCT} = \text{EAT} + \text{Condenser split}$$

EXAMPLE 47-2: SOLVING FOR OPERATING RCT

Using the formula with 95°F EAT, the operating RCT for the various EER systems would be as follows:

For an EER rating of 7.0 to 8.0, the condenser split is typically 25 to 30°F

$$\text{Operating RCT} = 95^\circ\text{F} + (25 \text{ to } 30^\circ\text{F}) = 120 \text{ to } 125^\circ\text{F}$$

For an EER rating of 8.0 to 9.0, the condenser split is typically 20 to 25°F

$$\text{Operating RCT} = 95^\circ\text{F} + (20 \text{ to } 25^\circ\text{F}) = 115 \text{ to } 120^\circ\text{F}$$

47.8 REFRIGERANT SUBCOOLING

The amount of subcooling produced in the condenser is affected by the quantity of refrigerant in the system. The temperature of the air entering the condenser and the load on the DX coil also has an effect on the amount of subcooling produced. Typically, it is desirable to have liquid subcooling of approximately 15–20°F.

If a refrigerant liquid line rises over 30 ft vertically, additional subcooling may be required to ensure that the metering device is receiving 100 percent liquid. The additional subcooling is required because of the pressure difference between the refrigerant at the condenser and pressure of the refrigerant at the metering device. This pressure drop is the result of the static head caused by the vertical lift of the refrigerant. Refer to the manufacturer's technical specifications to see what additional subcooling is required for unusually high vertical lifts.

47.9 INSUFFICIENT OR UNBALANCED LOAD

Insufficient air over the DX coil would be indicated by a greater than desired temperature drop through the coil. An unbalanced load on the DX coil would also give the opposite indication—some of the circuits of the DX coil would be overloaded, while others would be lightly loaded. This would

result in a mixture of air off the coil that would cause a reduced temperature drop of the air mixture. The lightly loaded sections of the DX coil would allow liquid refrigerant to leave the coil and enter the suction manifold and suction line.

TECH TIP

The final step of installation that takes place at the residence is outside the control of the manufacturer. Many manufacturers have found that significant problems can exist in system installation, including the mismatching of equipment sizes. If you suspect that your refrigerant circuit problems are the result of mismatched equipment, call the equipment supplier or manufacturer and provide them the system component model numbers so they can inform you as to whether the system is mismatched in size and make recommendations to resolve the problems if a mismatched system exists.

In TEV systems, the liquid refrigerant passing the sensing bulb of the TEV would cause the valve to close down. This would reduce the operating temperature and capacity of the DX coil and lower the suction pressure. This reduction would be very pronounced. The DX coil operating superheat would be very low, probably zero, because of the liquid leaving some of the sections of the DX coil.

Discharge pressure (high side) would be low due to the reduced load on the compressor, reduced amount of refrigerant vapor pumped, and reduced heat load on the condenser. Condenser liquid subcooling would be higher than normal because of the reduction in refrigerant demand by the TEV. The condensing unit amperage draw would be down due to the reduced load.

In systems using fixed metering devices, the unbalanced load would produce a lower temperature drop of the air through the DX coil because the amount of refrigerant supplied by the fixed metering device would not be reduced; therefore, the system pressure (boiling point) would be approximately the same.

The DX coil superheat would drop to zero with liquid refrigerant flooding into the suction line. Under extreme cases of imbalance, liquid returning to the compressor could cause compressor damage. The reduction in heat gathered in the DX coil and the decrease of refrigerant vapor to the compressor will lower the load on the compressor. The compressor discharge pressure will be reduced.

The flow rate of the refrigerant will only be slightly reduced because of the lower discharge pressure. The subcooling of the refrigerant will be in the normal range. The amperage draw of the condensing unit will be slightly lower because of the reduced load on the compressor and reduction in head pressure.

47.10 EXCESSIVE LOAD

In the case of excessive load, the opposite effect exists. The temperature drop of the air through the coil will be less, because the unit cannot cool the air as much as it should.

Air is moving through the coil at too high a velocity. There is also the possibility that the temperature of the air entering the coil is higher than the return air from the conditioned area. This could be from air leaks in the return duct system drawing hot air from unconditioned areas.

The excessive load raises the suction pressure. The refrigerant is evaporating at a rate faster than the pumping rate of the compressor. If the system uses a TEV, the superheat will be normal to slightly high. The valve will operate at a higher flow rate to attempt to maintain superheat settings. If the system uses fixed metering devices, the superheat will be high. The fixed metering devices cannot feed enough refrigerant to keep the DX coil fully active.

The discharge pressure will be high. The compressor will pump more vapor because of the increase in suction pressure. The condenser must handle more heat and will develop a higher condensing temperature. A higher condensing temperature means a greater discharge pressure. The quantity of liquid in the system has not changed, nor is the refrigerant flow restricted. The liquid subcooling will be in the normal range. The amperage draw of the unit will be high because of the additional load on the compressor.

47.11 LOW AMBIENT TEMPERATURE

In this case, the condenser heat transfer rate is excessive, producing an excessively low discharge pressure. As a result, the suction pressure will be low because the amount of refrigerant through the metering device will be reduced. This reduction will reduce the amount of liquid refrigerant supplied to the DX coil. The coil will produce less vapor and the suction pressure drops.

SERVICE TIP

Often air-conditioning and refrigerant equipment dies at night. This is frequently because of the lower ambient temperatures experienced in the evening. Low ambient operation of refrigeration and air-conditioning compressors can result in a liquid floodback or slugging of the compressor. If a system is to be operated on a regular basis during low ambient conditions, it should be equipped with a low ambient kit to protect the compressor.

The decrease in the refrigerant flow rate into the coil reduces the amount of active coil, and a higher superheat results. In addition, the reduced system capacity will decrease the amount of heat removed from the air. There will be a higher temperature and relative humidity in the conditioned area, and the discharge pressure will be low. This starts a reduction in system capacity. The amount of subcooling of the liquid will be in the normal range. The quantity of liquid in the condenser will be higher, but the heat transfer rate of the evaporator is less. The amperage draw of the condensing unit will be less because the compressor is doing less work.

The amount of drop in the condenser ambient air temperature that the air-conditioning system will tolerate

depends on the type of pressure-reducing device in the system. Systems using fixed metering devices will have a gradual reduction in capacity as the outside ambient drops from 95°F. This gradual reduction occurs down to 65°F. Systems that use a TEV will maintain higher capacity down to an ambient temperature of 47°F. Below these temperatures the capacity loss is drastic, and some means of maintaining discharge pressure must be employed to prevent the evaporator temperature from dropping below freezing. The most reliable means is control of air through the condenser via dampers in the airstream, the condenser fan cycling on and off, a variable-speed condenser fan, or some combination of these components.

47.12 HIGH AMBIENT TEMPERATURE

When the outside air temperature rises on a hot day, the temperature of the air entering the condenser will be higher. This also increases the condensing temperature and pressure of the refrigerant vapor. The suction pressure will also be high because the pumping efficiency of the compressor is reduced. There will also be less liquid-line subcooling, which will increase the amount of flash gas across the metering device, further reducing the system efficiency. Due to the high ambient temperature, the discharge pressure will be high. There will be less liquid refrigerant in the condenser and reduced liquid subcooling. The system will run less efficiently and therefore will require more power, so the amperage draw of the condensing unit will be high.

The amount of superheat produced in the coil will be different in a TEV system as compared to a system using a fixed metering device. In the TEV system, the valve will maintain superheat close to the limits of its adjustment range even though the actual temperatures involved will be higher.

In a fixed metering device system, the amount of superheat produced in the coil is the reverse of the temperature of the air through the condenser. The flow rate through the fixed metering device is directly affected by discharge pressure. The higher air temperature will result in a higher discharge pressure and a higher flow rate. As a result of the higher flow rate, the amount of subcooling in the condenser is lower.

Table 47-5 shows the superheat that will be developed in a properly charged air-conditioning system using a fixed

metering device. Do not attempt to charge a fixed metering device system below 65°F, as system operating characteristics become very erratic.

47.13 REFRIGERANT UNDERCHARGE

With a shortage of refrigerant in the system, less liquid refrigerant enters the evaporator coil to pick up heat, creating a lower suction pressure. The smaller quantity of liquid supplied to the coil results in less active surface for the evaporator coil for vaporizing the liquid refrigerant and more surface to raise vapor temperature. The superheat will be high. There will be less vapor for the compressor to handle and less heat for the condenser to reject, leading to a lower condensing temperature and discharge pressure.

SERVICE TIP

The compressor in an air-conditioning system is cooled primarily by the cool returning suction gas. Compressors that are low on charge can have a much higher operating temperature. The temperature can be high enough so that the motor windings begin to break down. As this occurs, the motor can ultimately short out, resulting in a compressor change-out. If an air-conditioning system has a leak, it must be located so that a low refrigerant charge can be avoided.

The amount of subcooling will be below normal to zero, depending on the amount of undercharge. The system operation is usually not affected very seriously until the subcooling is zero and hot gas starts to leave the condenser together with the liquid refrigerant. The amperage draw of the condensing unit will be slightly less than normal.

47.14 REFRIGERANT-OVERCHARGE TEV SYSTEMS

In systems using a TEV, the valve will attempt to control the refrigerant flow into the coil to maintain the superheat setting of the valve. However, the extra refrigerant will back up into the condenser, occupying some of the heat-transfer area that would otherwise be available for condensing. As a result, the discharge pressure will be slightly higher than normal, the liquid subcooling will be high, and the unit amperage draw will be high. The suction pressure and DX coil superheat will be normal. Excessive overcharging will cause even higher discharge pressure and hunting of the TEV.

SERVICE TIP

It is unacceptable to add a little extra refrigerant to a system just in case it may have a leak. If you suspect that a refrigeration system has a leak, do not overcharge the system; instead, find the leak and fix it.

Table 47-5 The Effects of Outdoor (Ambient) Temperature on Superheat

Figure 47-24 The effect of the refrigerant charge on the capacity of the unit.

47.15 REFRIGERANT OVERCHARGE IN FIXED METERING DEVICE SYSTEMS

The amount of refrigerant in the fixed metering system has a direct effect on system performance. An overcharge has a greater effect than an undercharge, but both affect system performance, EER, and operating cost.

As shown in Figure 47-24, at 100 percent of correct charge (55 oz), the unit developed a net capacity of 26,200 BTU/hr. When the amount of charge was varied 5 percent in either direction, the capacity dropped as the charge varied.

Figure 47-25 is a chart showing the amount of electrical energy the unit will demand because of pressure created by

Figure 47-25 The effect of the refrigerant charge on the kW demand of the condensing unit.

Figure 47-26 The effect of the refrigerant charge on the BTU/hr/kW ratio.

the amount of refrigerant in the system, with the only variable being the refrigerant charge. At 100 percent of charge (55 oz) the unit required 32 kW. As the charge was reduced, the wattage demand also dropped. When the unit was overcharged, the wattage required went up.

Figure 47-26 shows the EER of the unit based on the BTU/hr capacity of the system versus the wattage demand on the condensing unit. At the correct charge (55 oz), the EER was 8.49. As the refrigerant charge is either reduced or overcharged, the EER drops. From these charts, the only conclusion is that the capillary-tube systems must be charged to the correct charge with only a $\pm 5\%$ tolerance.

The effect of overcharge produces a high suction pressure because the refrigerant flow to the DX coil increases. Suction superheat will decrease because of the additional quantity to the DX coil. At approximately 8–10 percent of overcharge, the suction superheat becomes zero and liquid refrigerant will leave the DX coil. This will cause flooding of the compressor and greatly increases the chance of compressor failure. The discharge pressure will be high because of the extra refrigerant in the condenser. Liquid subcooling will also be high for the same reason. The amperage draw will increase due to the greater amount of vapor pumped as well as the higher compressor discharge pressure.

47.16 LIQUID-LINE RESTRICTION

A liquid-line restriction could be caused by a plugged liquid-line drier, a kink in the liquid line, or a solder joint filled with solder. A liquid-line restriction reduces the amount of refrigerant to the metering device. The suction pressure will be low because of the reduced amount of refrigerant to the DX coil. The suction superheat will be high because of the reduced active portion of the coil, allowing more coil surface for increasing the vapor temperature as well as reducing the refrigerant boiling point. The discharge pressure will be low because of the reduced load on the compressor. Liquid subcooling will be high. The liquid refrigerant will accumulate in the condenser. It cannot flow out at the proper rate because of the restriction. As a result, the liquid will cool more than desired. The amperage draw of the condensing unit will be low.

SERVICE TIP

If the symptoms indicate that there is a liquid-line restriction, it is sometimes easy to identify the liquid-line drier as the problem. As the refrigerant flow is reduced through the drier due to the restriction, the pressure of the refrigerant will drop. This reduction in pressure across the drier will produce some flash gas, similar to the situation that occurs across a capillary tube or TEV. The drier will be much colder on its outlet as compared to its inlet. A severely blocked drier may have frost accumulation on its outlet.

47.17 PLUGGED PRESSURE-REDUCING DEVICE

Either a plugged fixed metering device or plugged feeder tube between the TEV valve distributor and the coil will cause part of the coil to be inactive. The system will then be operating with an undersized coil.

Plugged Fixed-Bore or Capillary-Tube Metering Devices

The suction pressure will be low because the coil capacity has been reduced. The reduced amount of vapor produced in the coil and resultant reduction in suction pressure will reduce compressor capacity, discharge pressure, and the flow rate of the remaining active capillary tubes. The suction superheat will be high. The discharge pressure will be low. The liquid subcooling will be high because the liquid refrigerant will accumulate in the condenser. The unit amperage draw will be low. The possibility of moisture in the system that freezes and plugs the capillary orifice should be considered.

Plugged TEV Feeder Tube

A plugged feeder tube reduces the capacity of the coil. The coil cannot provide enough vapor to satisfy the pumping capacity of the compressor, and the suction pressure balances out at a low pressure. The remaining symptoms are similar to those of a plugged fixed metering device except that the superheat will be in the normal range. The TEV will adjust to the lower operating conditions and maintain the set superheat range.

47.18 SUCTION-LINE RESTRICTION

A suction-line restriction could be caused by a plugged suction-line strainer, a kink in the suction line, or a solder joint filled with solder. It results in a high-pressure drop between the DX coil and the compressor.

The suction pressure, as measured at the condensing unit end of the suction line, will be low. The superheat, as determined from the suction-line temperature at the DX coil and the suction pressure (boiling point)

at the condensing unit, will be extremely high. The discharge pressure will be low because of the reduced load on the compressor. The amperage draw of the condensing unit will be low because of the light load on the compressor.

Be aware that the symptoms listed above usually indicate a refrigerant shortage. A major difference is that with a suction-line restriction, the subcooling will remain normal to slightly above normal. In an undercharged system, the amount of subcooling will be below normal to zero.

47.19 HOT-GAS-LINE RESTRICTION

For the condition of a gas-line restriction, the discharge pressure measured at the compressor outlet will be high and measured at the condenser outlet will be low. The suction pressure will be high due to the reduced pumping capacity of the compressor. The DX coil superheat is high because the suction pressure is high. Liquid subcooling is in the high end of the normal range. The compressor amperage draw will be above normal.

If the discharge pressure is only measured at the condenser outlet, the symptoms can be easily misinterpreted. High suction pressure and low discharge pressure will usually be interpreted as a low capacity compressor. However, the high amperage draw of the compressor indicates it is operating against a high discharge pressure. This will point toward a restriction between the outlet of the compressor and the pressure measuring point.

47.20 LOW-CAPACITY COMPRESSOR

The problem of a low-capacity compressor is last on the list because it is the least likely problem. Determining the age of the unit may be useful, as an older compressor is more likely to have a reduced efficiency. When the compressor will not pump the required amount of vapor, the suction pressure will balance out higher than normal. The DX coil superheat will be high. The discharge pressure measured at the compressor outlet will be low. Liquid subcooling will be low because not much heat will be in the condenser. The condensing will therefore be close to the entering air temperature. The amperage draw of the condensing unit will be extremely low, indicating that the compressor is doing very little work.

UNIT 47—SUMMARY

The referral to a troubleshooting chart will assist in locating the cause of the problem. As soon as the cause is verified, in most cases the remedy is self-evident. For example, if a wiring connection is loose, it needs to be

tightened. When a motor is burned out, it needs to be replaced. Where the replacement or service of specialized parts is required, usually the manufacturer provides detailed instructions for performing the work. When maintenance is required, such as cleaning a dirty coil or replacing worn-out belts, these should be done following recommended standard procedures.

WORK ORDERS

Service Ticket 4701

Customer Complaint: Room Temperature Too High

Equipment Type: Residential Split Air-Conditioning System

A technician is called out to service a split air-conditioning system with an air handler and coil located in the attic. The technician arrives on the job, speaks to the customer, and discovers that the room temperature has been slowly rising during the past 3 to 4 weeks. The room temperature is higher than the thermostat setpoint, the air handler blower is running normally, and the outside condensing unit and compressor both appear to be running continuously.

The technician then measures the high- and low-side refrigerant system pressures, and they are both low. The compressor amperage draw is also low. The technician suspects that there may be a refrigerant leak, which has led to a shortage of refrigerant. Upon once again speaking with the customer, the technician discovers that some landscaping had been done about 3 weeks ago. Investigating the outside lines that lead into the home, the technician finds that the liquid line had been disturbed, and, using a leak detector, a leak is located in the area of a brazed fitting. The refrigerant will need to be recovered, the leak repaired, and the system evacuated and recharged.

Service Ticket 4702

Customer Complaint: Low Register Airflow

Equipment Type: Residential Split Air-Conditioning System

A technician is called out to service a split air-conditioning system with an air handler and coil located in the attic. The technician arrives on the job, speaks to the customer, and learns that the air flow through the registers seems very low. Even without taking a measurement, it is easy to feel along the register and determine that not much air is being delivered. The customer also tells the technician that the system has just been started for the summer season about a week ago and that it has not worked well from that time.

The technician decides to first check the air-handling unit in the attic, suspecting a clogged filter to

be the problem. Upon investigating the unit, the technician discovers that squirrels had found an opening in the duct and built a nest in the path of the airflow during the winter months. The technician recommends that the customer contact an exterminator to remove the pests. Once this is done, the technician can come back and replace the filters and repair the duct.

Service Ticket 4703

Customer Complaint: Water Leaking from Ceiling

Equipment Type: Residential Split Air-Conditioning System

A technician is called out to service a split air-conditioning system with an air handler and coil located in the attic. The technician arrives on the job and speaks to the customer, who says that there is water leaking from the attic and it has stained his ceiling. The customer believes that the water is coming from the air-conditioning unit.

The technician is not sure whether this may be a humidity-related problem and first decides to check the air-handling unit in the attic. The technician quickly discovers that the coil drain pan is overflowing and has caused the stain. A section of the drain piping is blocked, and the technician cuts it out and replaces it. Once the blocked section is replaced, the water drains normally without backing up. The technician then recommends that the customer approve the installation of a float switch in the evaporator coil drain pan that will shut the unit down in the event of a similar occurrence in the future. This would reduce the chance of water ruining the ceiling again after the stain has been removed.

UNIT 47—REVIEW QUESTIONS

1. How is the temperature drop through a DX coil on an air-conditioning system determined?
2. What is the most common problem of air failure on an air-conditioning system?
3. If a split air-conditioning system does not operate at all, the problem is most likely what?
4. If an electrical load on an air-conditioning system is not working, what must the technician try to determine?
5. What does an electrical connection diagram show?
6. List the measurements that need to be taken to determine the extent of a mechanical problem in an air-conditioning system.
7. How are normal coil operating temperatures for an air-conditioning system determined?
8. How does condenser size affect the EER?
9. What has the predominant effect on the amount of subcooling produced in the condenser of an air-conditioning system?
10. What should be done if you suspect problems due to mismatched equipment sizes on a split air-conditioning system?

11. What type of temperature drop would you expect across the DX coil on an air-conditioning system with insufficient airflow?
12. What will happen to the suction pressure on an air-conditioning system that is running with an excessive load?
13. Why do split air-conditioning systems often fail during the night?
14. A split air-conditioning system that uses a fixed metering device should not be charged if the ambient temperature falls below what level?
15. Capillary-tube systems must be charged to within what tolerance?
16. What happens to the refrigerant superheat if an air-conditioning system using a capillary tube is overcharged?
17. What happens to the amperage draw of a condensing unit on an air-conditioning system if the liquid line is restricted?
18. How can one determine between a refrigerant shortage as compared to a suction-line restriction on a split air-conditioning system?
19. How can you determine between an inefficient compressor as compared to a hot-gas line restriction on a split air-conditioning system?
20. Is it acceptable to add a little extra refrigerant to a system just in case it may have a leak?

UNIT 48

Principles of Combustion and Safety

OBJECTIVES

After completing this unit, you will be able to:

1. list the most common types of fuel gases and compare their properties.
2. list the three essential components of complete combustion.
3. describe the two types of flame and list their characteristics.
4. list the products of complete combustion.
5. explain how CO is produced and how to keep CO out of combustion gases.
6. explain the combustion air requirements for gas furnaces.
7. define AFUE.
8. list the certifying agencies for gas-fired equipment.

48.1 INTRODUCTION

Nothing heats like fire. A large percentage of all home heating is provided by gas-fired heating systems. Gas flames provide large quantities of clean heat. A thorough understanding of the principles of combustion is necessary for technicians to safely work with gas and to keep gas-fired equipment operating safely and cleanly.

Safety should always be the primary concern for a technician when working with combustible gases. Safety starts with understanding the behavior of combustible gas and the principles of combustion. Technicians need to know the requirements for safe operation and recognize potential hazards. Customers depend on the technician to keep their gas-fired equipment operating safely and efficiently.

48.2 FUEL GASES

Fuel gases are used for many heating and air-conditioning processes and fall into three broad categories: natural, manufactured, and liquefied petroleum. Stories about the discovery and use of natural gas date back as far as 2000 BC. History notes that the Chinese piped gas from shallow wells through bamboo poles to boil seawater to obtain salt.

The great advantage of natural gas over other fuels is its relative simplicity of production, transportation, and use. When a sufficiently large quantity is discovered, it is pumped from drill wells to processing plants and on to refineries and industrial centers, where it has a large number of diverse uses in addition to heating (Figure 48-1).

THE NATURAL GAS INDUSTRY

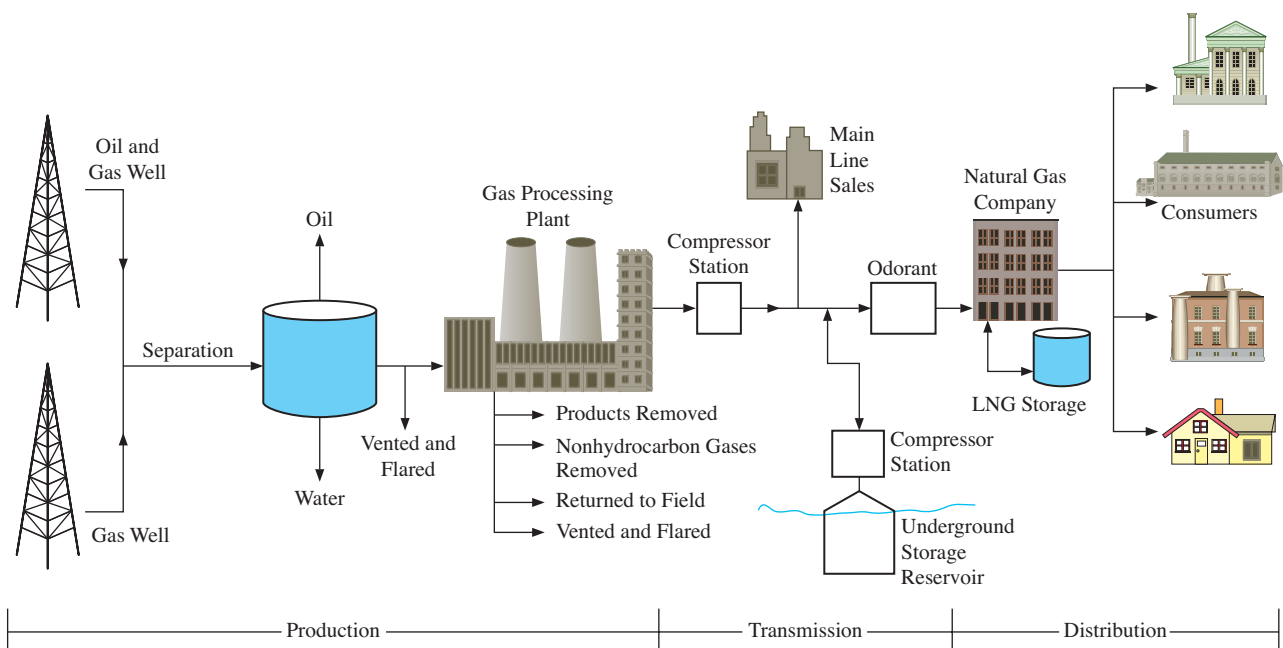

Figure 48-1 Natural gas distribution. (Courtesy of the Energy Information Administration, Washington, DC)

PETROLEUM AND NATURAL GAS FORMATION

Figure 48-2 Formation of natural gas. (Courtesy of the Energy Information Administration, Washington, DC)

Natural gas comes from the sedimentation of trillions of tiny organisms at the bottom of the sea that are buried and initially chemically converted into dense organic material. Over millions of years, pressure and heat gradually cracked this material into lighter hydrocarbon compounds. Liquids were liberated first, then the gases. Compaction squeezed these products from the source rock and they each migrated into the more porous reservoir rocks until stopped by impermeable barriers. Pools of gas and oil developed that are the targets of petroleum exploration (Figure 48-2).

Most fuel gases are hydrocarbons; they are made entirely of carbon and hydrogen (Figure 48-3).

The carbon atoms link to each other in a chain and are surrounded by hydrogen atoms. Table 48-1 shows properties of the most common hydrocarbons used in heating.

Natural gas comes out of the ground while liquid petroleum (LP) gases are the result of distillation. Natural gas is mostly methane, but it also contains other gases in small quantities, including ethane, propane, and butane (Figure 48-3).

LP gases are propane, butane, or a mix of the two. These fuel gases are obtained from natural gas or as a by-product of refining oil. Propane is the LP gas mostly used for domestic heating. Butane has more agricultural and industrial applications. Figure 48-3 shows that propane and butane contain more carbon and hydrogen atoms than natural gases. LP gases are heavier and have more heating value per cubic foot than natural gas because of their increased number of carbon and hydrogen atoms. LP gas

Figure 48-3 Chemical components of common fuels; natural gas is mostly methane and ethane, and LP is mostly propane and/or butane.

is stored and transported in liquid form. Unlike natural gas, LP is not transported through a network of pipelines. LP is shipped long distances on rail tankers and across shorter distances by tanker trucks. LP is delivered to the customer where it is pumped from the truck into the customer's storage tank (Figure 48-4). LP tends to be more expensive than natural gas because it must be refined and its delivery cost is higher.

Manufactured gas, as the name states, is manmade as a byproduct of other manufacturing operations. The use of manufactured fuel gases has declined greatly in the United States. Today over 99 percent of sales by gas-distribution and -transmission companies is natural gas. Manmade gas is still a popular fuel in Europe.

Table 48-1 Ultimate CO_2 Values, Flammable Limits of Fuels, and Heating Values of Fuels

Constituent	Chemical Formula	Ultimate CO_2 (%)	Lower Flammability Limit (%)	Upper Flammability Limit (%)	Ignition Temperature ($^{\circ}\text{F}$)	Higher Heating Values (BTU/lb)	Lower Heating Values (BTU/lb)	Specific Volume (ft^3/lb)
Methane	CH_4	11.73	5.0	15.0	1,301	23,875	21,495	23.6
Ethane	C_2H_6	13.18	3.0	12.5	968–1,166	22,323	20,418	12.5
Propane	C_3H_8	13.75	2.1	10.1	871	21,669	19,937	8.36
Butane	C_4H_{10}	14.05	1.86	8.41	761	21,321	19,678	6.32

(a)

(b)

Figure 48-4 (a) 100-gallon refillable propane tank for residential use; (b) tank level gauge for use with propane, butane, or 50/50 mix.

Mixed gas, as the name implies, is a manmade mixture of gases such as natural gas and manufactured gas.

It is important to know the density of a gas as expressed by its specific gravity. The specific gravity of a gas compares its density to the density of air. Standard air has a specific gravity of 1.0. The specific gravity of natural gas ranges from 0.4 to 0.8, making it lighter than air, as shown in Figure 48-5.

On the other hand, the specific gravity of propane is 1.5 and butane is 2.0. This means they are heavier than air (Figure 48-6). The specific gravity of the gases is important because it affects the flow of the gas through orifices (small holes) and then to the burner. Should a leak develop in a gas pipe, natural gas will rise and probably dissipate, while LP gases will drift to low spots and collect in pools, creating a greater hazard. Specific gravity also affects gas flow in supply pipes and the pressure needed to move the gas.

Figure 48-5 Weight of 1 ft³ of air compared to 1 ft³ of natural gas.

Figure 48-6 Weight of 1 ft³ of air compared to 1 ft³ of propane.

SAFETY TIP

Because LP gases are heavier than air, they collect in low areas. A leak in the gas line to an LP furnace in a crawlspace or basement will create a “puddle” of gas on the ground around the furnace. An unwary technician could be lying in this puddle of LP gas when it is ignited, surrounding the technician in flames.

The heat value of a gas is the amount of heat released when 1 ft³ of the gas is completely burned (Figure 48-7).

Natural gas has a heating value range of 950 to 1,150 BTU/ft³. The range of BTU per cubic foot for natural gas is because it is a mixture of gases, with methane making up the largest share. The heat value of 1,000 BTU/ft³ is most often used for estimating performance for natural gas furnaces. Propane has a heat value of approximately 2,500 BTU/ft³; butane’s heat value is 3,200 BTU/ft³. The exact heating value of gases in your local area can be obtained from the gas company or LP gas distributor.

Figure 48-7 Heat delivered by gas fuels when burned.

Figure 48-8 The three things that must be present for combustion to occur are fuel, heat, and oxygen.

48.3 FUEL GAS COMBUSTION

Combustion is a term used to describe rapid oxidation. Oxidation is a chemical reaction between oxygen and another substance that produces a new compound and releases heat. Three ingredients are required for combustion: fuel, oxygen, and heat (Figure 48-8).

An example of combustion is the reaction between carbon and oxygen. They combine to form carbon dioxide. Great amounts of heat are generated within a short period of time because of the speed of the reaction.

TECH TIP

Large quantities of water vapor are produced as a product of combustion. The heating value of a fuel can be increased approximately 10 percent by condensing this water vapor from the flue gases. This is how manufacturers produce furnaces with efficiencies of 90–97 percent.

Most gaseous fuels consist of different mixtures of hydrocarbons. When oxygen and hydrocarbons are combined, water and carbon dioxide are produced. Both are extremely stable and safe compounds. The combustion of methane gas is illustrated in Figure 48-9. But if the reaction does not take place under the proper conditions (i.e., the correct temperature and gas-to-air ratio), then variable amounts of unstable and often toxic substances are produced due to incomplete combustion. Definite oxygen-to-hydrocarbon ratios are required for complete combustion; insufficient

Figure 48-9 Combustion process when a fuel is burned.

Figure 48-10 Amount of air required for combustion of methane compared to propane.

oxygen will produce incomplete combustion. For every 1 ft³ of methane gas, 10 ft³ of air is needed for complete combustion (Figure 48-10). Although natural gas requires a 10:1 ratio of air, LP fuels require much more, due to the concentration (greater density) of carbon and hydrogen atoms. Propane combustion must have more than 24 ft³ of air per 1 ft³ of gas to support proper combustion. When complete information about the fuel is not available, a frequently used value for estimating air requirements is that 0.9 ft³ is required for 100 BTU of fuel.

In modern atmospheric burners, the combustion air enters the reaction at two separate points (Figure 48-11). These are called atmospheric burners because the air for the burning process is at atmospheric pressure. *Primary air* refers to air that is mixed with the fuel before the fuel is ignited. *Secondary air* refers to air that is drawn into the combustion process after the fuel has ignited. Air is introduced into the combustion process at two levels because of the difficulty in maintaining an exact mixture of oxygen and fuel before combustion. Primary air and secondary air

Figure 48-11 Cross-section of a gas burner.

Figure 48-12 Natural gas flames: (a) correct mixture of fuel and air; irregular, (b) less primary air, cone reduced; (c) less primary air, flame wider; (d) less primary air, flame more irregular; (e) too little primary air, irregular, wide flame.

are generally referred to together as combustion air since they usually do come from the same place.

Heat is needed as a catalyst to initiate and maintain the combustion process. Without sufficient heat, the combustion process will not start; or, if started, it will result in incomplete combustion. Complete combustion occurs when the correct ratio of fuel and oxygen combine at a sufficiently high temperature to use up all the fuel, producing only water and carbon dioxide.

Incomplete combustion produces carbon monoxide (CO), an odorless, tasteless, and poisonous gas. Any condition that results in incomplete combustion should be corrected immediately.

48.4 TYPES OF FLAMES

Basically there are two types of flames: yellow and blue (Figure 48-12). The difference is mainly due to the manner in which the fuel is mixed with the air. A yellow flame is produced when gas is burned by igniting it as it gushes from an open end of a gas pipe, such as is common for ornamental lighting. Yellow flames are characteristic of luminous combustion; a process that produces a little heat, lots of light, and lots of carbon monoxide. A yellow flame indicates incomplete combustion.

Modern gas burners will burn with a blue flame. A blue flame is produced by a Bunsen burner such as those used

in a laboratory, where 50 percent of the air requirement is mixed with the gas prior to ignition. Blue flames are characteristic of nonluminous combustion, a process that produces a little light, lots of heat, and no carbon monoxide. Complete combustion is indicated by an inner blue cone (Figure 48-13).

The manifold and gas spuds (Figure 48-14) are used on nearly 80 percent of gas furnaces.

A good example of the use of primary and secondary air is shown in Figure 48-11. This figure shows the primary air adjustment on a drilled burner port. The gas is supplied through a manifold and metered into the burner by a properly selected gas orifice. The air enters through adjustable openings around the gas orifice. The velocity of the gas jet creates a low-pressure area around it, which draws in

Figure 48-13 Inner blue cone indicates complete combustion.

Figure 48-14 Gas burner manifold.

primary air. The gas and primary air pass through a toilet-bowl-shaped venturi. The venturi causes the gas and air to swirl as they pass through it, mixing them together. The secondary air is drawn in by the draft created from the flames. When the air supplies are properly adjusted for complete combustion, the burner operates with a blue flame.

48.5 PRACTICAL COMBUSTION CONSIDERATIONS

Perfect combustion will result in no leftover fuel, oxygen, or unstable compounds. Since absolute perfection in the gas-to-air ratio is not possible, most appliances introduce excess combustion air to ensure that no fuel or unstable compounds are left. Excess oxygen is left, which reduces combustion temperatures and lowers combustion efficiency. This is the tradeoff for safer operation. An absolute minimum of 10 percent excess air is required for safe operation. Practice has shown that 40–50 percent excess air provides safe operation in natural draft systems. This means that 14–15 ft³ of combustion air per 1,000 BTU are needed for complete combustion and safe operation of a natural gas-fired appliance. The effect of excess air on combustion efficiency is shown in Table 48-2.

The heat catalyst is still required before complete combustion can take place. Methane, the primary component in natural gas, will ignite at temperatures as low as 1,076°F and can reach temperatures as high as 3,500°F. In general, a temperature of 1,200°F is the absolute minimum tem-

perature to be maintained to keep the process going and achieve complete combustion. Commercial gas is almost always diluted with other gases, and its minimum combustion temperature is usually between 1,200°F and 1,220°F. But most appliances actually operate between 1,600°F and 1,800°F to compensate for the temperature drop in the combustion chamber due to the introduction of excess air. The heat carried away by the excess air represents an efficiency loss, but it is necessary in an atmospheric burner to ensure complete combustion.

The byproducts of combustion in furnaces are called flue gases and are vented to the outside. Insufficient combustion air can produce hazardous conditions. If too little oxygen is supplied, part of the byproducts will be dangerous carbon monoxide gas (CO) rather than harmless carbon dioxide gas (CO₂). The lack of combustion air can also keep a natural draft vent from operating, stopping the flue gases from rising up the flue. Vent gases then begin to spill into the room. These flue gases in a living area cause serious health problems. Adequate combustion air is an essential element of the system's design and central to indoor air quality.

Air quality can be greatly affected by the formation of nitrous oxides. Nitrogen represents about 80 percent of the earth's atmosphere. Therefore, in conjunction with the excess air necessary for complete combustion, it is clear that nitrogen constitutes the major portion of the exhaust gases. Nitrogen is practically inert; however, at the temperatures generated in the combustion chamber, nitrogen is no longer inactive, and oxygen and nitrogen will react to form oxides of nitrogen (NO_x). The two factors that most significantly influence the formation of NO_x are temperature and oxygen concentration. A rule of thumb says that a temperature change of 212°F may change the NO_x amount by a factor of 3.

Oxides of nitrogen in the atmosphere contribute to smog formation, which is considered to be a problem in many urban areas. Also, the conversion of NO to NO₂ will continue in the atmosphere and, as NO₂ is soluble in water, it will be washed out of the air by rain, creating undesirable acidic conditions. Oxides of nitrogen are also of concern because they are believed to be carcinogenic. Due to these factors, some cities and states require furnaces that have lower nitrous oxide values. They are referred to as low-NO_x furnaces.

Table 48-2 Effect of Excess Air on Combustion Efficiency

		Combustion Efficiency				
		Flue Gas Temperature Less Combustion Air Temp, °F				
Excess %						
Air	Oxygen	200	300	400	500	600
9.5	2.0	85.4	83.1	80.8	78.4	76.0
15.0	3.0	85.2	82.8	80.4	77.9	75.4
28.1	5.0	84.7	82.1	79.5	76.7	74.0
44.9	7.0	84.1	81.2	78.2	75.2	72.1
81.6	10.0	82.8	79.3	75.6	71.9	68.2

(Courtesy of the U.S. Department of Energy)

TECH TIP

Furnaces require a significant amount of combustion air. During new construction, the quantity of air required is carefully checked and inspected; however, over time in older residences insulation or other debris can inadvertently fall over the makeup-air vents for a furnace. When this happens it can adversely affect the furnace performance and create a potential safety problem. This problem is particularly a concern when the furnace is located inside of a dwelling space in an equipment closet. If the closet door is properly sealed, the lack of proper makeup air will be negated when the technician has the door to the furnace closet open for service. Therefore, technicians must visually inspect makeup-air vents to make sure they are free and open.

48.6 GAS SAFETY

The storage and distribution of gas should always follow all federal, state, and local code requirements. Even a small gas leak has the potential for massive destruction. In 2011, a natural gas blast in the United States demolished two houses, set fire to several more, and sent flames hundreds of feet into the air. By the time the fire was extinguished, six more homes were lost and over five hundred people were evacuated from the area.

Always inform your customer of the risks associated with gas. Alert them to some basic safety procedures if they smell gas:

- Do not try to light any appliance.
- Do not touch any electrical switch.
- Do not use any telephones in the building.
- Leave the building immediately.
- Call the gas supplier from a neighbor's phone or cell phone once outside and far away from the building.
- If the gas supplier cannot be reached, call the fire department.

Carbon Monoxide Poisoning

Never take any unnecessary risks when working with gas. Always read the equipment manual and follow all the manufacturer's safety recommendations. Devices that use gas as a fuel must be vented properly to the outdoors. Never allow the flue gases to enter the living spaces. These contain carbon monoxide, which is invisible, odorless, and toxic. Carbon monoxide detectors installed in the living spaces will alarm and alert the occupants before the carbon monoxide levels are allowed to reach toxic levels.

SAFETY TIP

Furnace vents are not allowed to be shared by any other appliances. Improper venting will allow combustion gases to collect in the building, which may lead to nausea and even death by asphyxiation.

Air Supply

Fuel-burning appliances require sufficient quantities of air for proper combustion and ventilation of the flue gases. Gas furnaces require air for combustion, and this should be taken from outside the living space. Make sure that combustion supply air is not blocked and adequate space is allowed around the exterior of the furnace. Common signals indicating insufficient supply air include the following:

- Complaints of headache, nausea, and dizziness
- Excessive humidity levels indicated by heavily frosted windows or a moist, "clammy" feeling in the living spaces
- For homes that have fireplaces, the smoke does not draw up the chimney properly and puffs back

Negative Building Pressure

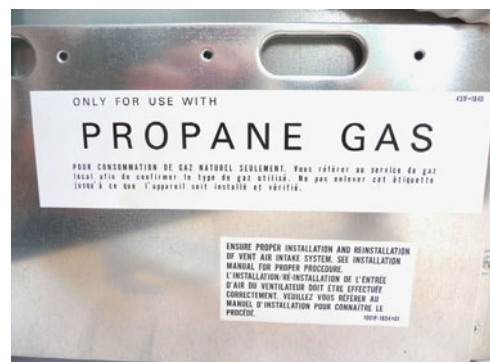

The use of exhaust fans, fireplaces, clothes dryers, and other appliances will use air or vent air to the outdoors. This, along with new weather stripping, storm windows, and added insulation, can lead to negative pressure in the building. This negative pressure can allow for combustion gases and flue gases to more readily escape from leaks in the furnace. More outside air will need to be brought into the building to correct this condition.

Propane

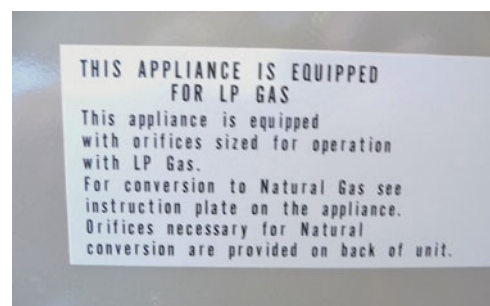

Propane gas is heavier than air; therefore, leaking gas will settle into a low area. Propane is an odorless gas, but a distinct pungent aroma is added to it by the refinery to help detect leaks. Some furnaces come equipped to burn either natural gas or propane. Each gas requires a different size burner orifice. When converting from one gas to the other or when setting up a new system, make sure that the proper orifice kit is installed. Orifices are stamped to provide the size (twist drill number). Oversized orifices could result in hazardous conditions, especially if the ventilation is inadequate. Most new furnaces will have a label to designate the type of gas it has come equipped to handle (Figure 48-15).

SAFETY TIP

At high elevations, typically above 2,000 feet, the furnace input rating must be adjusted and the size of the burner orifices recalculated based on elevation and gas heating value. The burner orifices may (or may not) need to be changed.

(a)

(b)

Figure 48-15 (a) Label for gas heater indicating propane gas use only; (b) label on gas heater providing orifice information.

Figure 48-16 Bank of gas meters and pressure regulator located outside an apartment complex.

Gas Pressure and Input Rate

The gas supply pressure should be checked with all the appliances attached to the gas supply line turned on. If possible, a separate gas supply line should be run directly from the meter to the furnace. The gas pressure required for natural gas is different than the pressure required for propane. Correct manifold gas pressure is required for proper ignition and burner operation. The input rate for natural gas furnaces can be measured by timing the gas meter (Figure 48-16). Propane gas installations do not have gas meters, and the input cannot normally be measured (Figure 48-17). Therefore, the proper gas pressure becomes even more critical (Figure 48-18).

Figure 48-17 Propane tanks have a pressure regulator located on the tank.

Figure 48-18 Gas valve on heater labeled with the correct input pressure for both natural gas and propane gas.

Gas Valves and Ignition

Make sure that flow is in the proper direction through the gas valve. There should be an arrow on the valve indicating the direction of gas flow. If flow is incorrect, the valve may not shut off, which can cause an uninterrupted gas flow and lead to a fire or explosion. Do not let fuel accumulate in the combustion chamber for longer than a few seconds without igniting. Fuel accumulation can lead to an explosion.

SAFETY TIP

Never attempt to manually light the burners with a match or other source of flame.

Checking for Gas Leaks

A gas leak check should be performed anytime work is done to the system. Isolate the furnace and gas control from the gas supply line during leak checks. This is because test pressures above $\frac{1}{2}$ psi (14 in wc) could damage the gas control valve, causing it to leak and resulting in fire or explosion. Once pressure is applied to the piping, a commercial soap solution made to detect leaks can be applied around all piping connections. The formation of bubbles indicates gas leakage.

SAFETY TIP

NEVER CHECK FOR GAS LEAKS WITH AN OPEN FLAME!

Garage Installations

Some furnaces are installed in residential garages. If this is the case, then the burners and ignition source must be located no less than 18 in above the floor. This is to reduce the risk of igniting flammable vapors that may be present in a garage. Also, the furnace must be located so that it is protected from being damaged by a moving vehicle.

Water Damage

Do not operate a furnace if any part has been underwater. The ignition module can malfunction if it gets wet, leading to accumulation of explosive gas. Never install where water can flood, drip, or condense on the module.

48.7 CONDENSATION AND CORROSION

The heating technician must always be on the lookout for problems caused by condensation and corrosion produced by the flue gases. When the fuel-burning system cycles on and off to meet the demand, the flue passages cool down during the off cycle. When the system starts up again, condensate forms briefly on the surfaces until they are heated above the dew-point temperature. Low-temperature corrosion can occur in exhaust system components (heat exchangers, flues, vents, chimneys).

Figure 48-19 Rusty furnace vent.

The condensate includes such corrosive substances as sulfides, chlorides, and fluorides.

Corrosion increases as the condensate dwell time increases. One of the common signs of this is the corrosion that takes place in the flue pipe between the furnace and the chimney. Even though a galvanized flue pipe is used, this piping needs to be replaced periodically due to the corrosion effect (Figure 48-19). Currently, a large number of gas-fired furnaces are located in an unheated garage, and with the use of single wall pipe and cold ambient air in the garage, condensation occurs in the long run, where it goes through the roof in double-wall pipe. Evidence of this condensation in the form of rust can be seen at the vent pipe joints and elbow joints. This condensation usually runs to the bottom of the heat exchanger, resulting in corrosion.

Type B double-wall vent pipe helps prevent condensation in the vent by keeping the inner wall warm. The small space between the inner and outer wall acts like insulation. Oversizing of the vent also contributes to condensation. The flue gases move slowly through an oversized vent, giving them more opportunity to cool and condense.

Older, less-efficient natural draft furnaces have an opening in the draft hood called a draft diverter. If the wind conditions produce a downdraft, the air is diverted away, so as not to disturb the pilot and main burner flames. However, under normal operation, dilution air is sucked into the draft diverter opening and mixed with the flue gases. The addition of dilution air reduces the percentage of water vapor in the gases, which lowers the dew point of the flue gases.

Newer 80 percent efficient furnaces operate with much lower temperature flue gases than older, less-efficient furnaces. They also do not have an open draft diverter, so no dilution air is introduced into the vent gases. Instead they are equipped with draft inducers and reduced levels of excess air. Therefore, because of their design, the newer 80 percent efficient furnaces are particularly susceptible to vent condensation. Because of this, these furnaces are generally not approved for venting through masonry chimneys. The water condensation mixed with the flue gases will lead to the formation of sulfuric acid. The acid will eat away at the mortar over time, leading to masonry failure. In addition, the condensation absorbed by the masonry can freeze and

Figure 48-20 Acid-neutralizing drain trap.

lead to breakup of the chimney. Using type B double-wall vent pipe is critical for these furnaces.

In the high-efficiency furnace where condensation is allowed to occur inside the furnace on a continuous basis, the flue passages must be constructed of corrosion-resistant materials such as stainless steel and PVC. The material used for condensate drains for high-efficiency furnaces is usually corrosion-resistant PVC. The condensate from a condensing furnace is slightly acidic, about the same as a carbonated beverage. Some cities require neutralizing the condensate before it enters the public sewers. Running it through a filter (Figure 48-20), which is basically a PVC cylinder filled with limestone rocks, does this. The acid eats the rocks, neutralizing the acid.

48.8 SOOT BUILDUP AND PATTERNS

Soot is a form of carbon, the result of incomplete combustion. Complete combustion binds all the carbon into carbon dioxide, but incomplete combustion leaves some carbon to form soot. Yellow flames make soot; blue flames do not make soot. Soot can be deposited on flue surfaces and acts as an insulating layer, reducing the heat transfer and lowering the efficiency (Figure 48-21). Soot can also clog flues, reduce draft and available air, and prevent proper combustion. A large buildup of soot can create a safety hazard, as it is

Figure 48-21 Soot deposits on heat exchanger.

very combustible! If the soot in a vent is ignited, the resulting fire in the vent can catch the house on fire.

A properly burning gas appliance will never make soot. Proper burner adjustment can prevent the formation of soot. Soot can be caused by too much fuel, too little air, or improper mixing. To prevent soot formation, the technician should do the following:

- Make sure the burner orifices are the correct size.
- Check the manifold gas pressure and adjust if necessary.
- Check the combustion air openings in the appliance room.
- Adjust the air shutters on the gas appliance to produce a blue flame.
- Perform a combustion analysis check.

48.9 AIR POLLUTION

The combustion processes constitute the largest single source of air pollution in a home. Some of the ways that the heating technician can help to reduce air pollution are as follows:

- Properly test installed furnaces and adjust the fuel-burning device for highest efficiency.
- Encourage the use of high-efficiency furnaces.
- Encourage the conservation of energy by recommending proper insulation and reduction of infiltration.
- Recommend the installation and operation of adequate outside air for ventilation and combustion.

Calculate the percentage of air required to determine if it meets guidelines:

$$\text{combustion air} = \frac{0.5 \text{ CFM}}{1,000 \text{ Btu}} \times \text{total Btu input}$$

To prevent air pollution, maintain clean plenum, air intakes, filters, ducts, and system components. And seal leaks, which is very important.

48.10 ANNUAL FUEL UTILIZATION EFFICIENCY (AFUE)

Furnaces are rated for their annual fuel utilization efficiency. This rating is obtained by applying an equation developed by the National Institute of Standards and Technology (NIST) for 100 percent efficiency and deducting losses for exhausted latent and sensible heat; the effects of cycling, infiltration; and the pilot burner effect. The AFUE is determined for residential fan-type furnaces by using the ANSI/ASHRAE Standard 103-1993 method of testing.

The federal law, effective January 1, 1992, requires that all new gas furnaces have a minimum AFUE efficiency of 78 percent. On June 27, 2011 the DOE published a direct final rule that splits the country into 3 regions: North, South, and Southwest. Beginning May 1, 2013, the minimum AFUE for furnaces in the South and Southwest regions will be 80% and the minimum AFUE for the North region will be 90%.

Most manufacturers offer two levels of furnace efficiency: 80 percent and 90 percent. There is no real difference in furnace cost between a 78 percent model and an 80 percent model, so very few 78 percent models are produced. Past experience has shown that furnaces operating at efficiencies higher than 80 percent AFUE are very likely to create condensation inside the heat exchanger or in the vent. Once a furnace passes the 80 percent threshold, the heat exchanger and vent must be designed to accommodate condensation, increasing the complexity of the furnace design. This limits low-end furnaces to 80 percent efficiency. The flue gas is too hot to use PVC vent material until the efficiency reaches 90 percent. So furnaces are basically available as 80 percent noncondensing furnaces and 90 percent condensing furnaces. Several manufacturers have tried to produce mid-efficiency furnaces with efficiencies between 80 and 90 percent, and the end result has always been unpleasant for contractors and customers. Some manufacturers also make super-efficiency models that exceed 90 percent, the highest being 98 percent.

The AFUE rating is only a basis of comparison. Obtaining that efficiency in any particular installation depends upon proper sizing and installation. Oversized furnaces will not deliver their rated efficiency due to the losses from heating up and cooling down the furnace. A smaller unit operating constantly will use less gas than a large unit cycling on and off. More operating efficiency can be gained by using a two-stage furnace. Operating on the lower firing rate allows for efficient operation. This is due in part to longer run cycles at a reduced capacity. This provides a closer track to the thermostat setpoint, ensuring a more comfortable environment. Table 48-3 shows the savings for every \$100 spent on fuel when upgrading to a higher-efficiency furnace. As an example, changing to a 95 percent AFUE from a 50 percent AFUE would save \$47 for every \$100 spent for fuel.

TECH TIP

Gas furnaces are designed to last for many years. Many that were built before the change in efficiency laws have AFUE ratings of 60 percent. Over time, these furnaces have lost some of that original efficiency and can be operating at a level well below 60 percent efficiency. Therefore, it is often in your customer's best interest if you recommend that they trade up to a newer higher-efficiency model. Doing so will both save them money and reduce air pollution.

48.11 CERTIFICATION OF HEATING EQUIPMENT

All types of heating apparatus sold domestically have to be tested, certified, or listed by accredited testing agencies such as AHRI, CSA International or Underwriters Laboratories, Inc. (UL). Gas appliances must meet standards set by a large number of governmental and independent agencies. Typically, the logos of the approving agencies can be found

Table 48-3 Savings from Upgrading to a Higher-Efficiency Furnace

		AFUE of New System				
AFUE of Existing System		75%	80%	85%	90%	95%
	50%	\$33	\$37	\$41	\$44	\$47
	55%	26	31	35	38	42
	60%	20	25	29	33	37
	65%	13	18	23	27	32
	70%	6	12	17	22	26
	75%		6	11	16	21
	80%			5	11	16
	85%				5	11

(Courtesy of the U.S. Department of Energy)

on the furnace nameplate. Some of these agencies just establish standards, while others perform testing to certify that equipment meets these standards. Three of these agencies, AHRI, CSA, and UL, are involved in both setting standards and certifying equipment.

Governmental Agencies

- **United States Department of Energy (DOE)** The primary governmental agency involved in gas furnace standards is the U.S. Department of Energy (DOE). One part of DOE's mission is to promote scientific and technological innovation in support of economic and energy security. DOE establishes the minimum AFUE that furnaces must meet. When developing their standards, DOE relies on research from two other governmental agencies: the National Institute of Standards and Technology (NIST) and the National Science Foundation (NSF).
- **National Institute of Standards and Technology (NIST)** Founded in 1901, NIST is a nonregulatory federal agency within the U.S. Commerce Department's Technology Administration. NIST's mission is to promote U.S. innovation and industrial competitiveness by advancing measurement science, standards, and technology in ways that enhance economic security and improve our quality of life. NIST establishes measurement standards of all types.
- **National Science Foundation (NSF)** The NSF is an independent federal agency created by Congress in 1950 "to promote the progress of science." NSF is the only federal agency whose mission includes support for all fields of fundamental science and engineering. NSF provides grants and oversight for basic science research.

Independent Agencies

- **Air-Conditioning Heating and Refrigeration Institute (AHRI)** AHRI is one of the largest trade organizations in the United States with over 300 member companies

responsible for producing more than 90 percent of the residential and commercial air conditioning, heating, water heating, and commercial refrigeration equipment made in North America. AHRI writes the equipment standards that most manufacturers use to rate their equipment. AHRI also independently certifies the performance and efficiency of air conditioning, heating, and refrigeration equipment. AHRI's certification programs comply with ISO Guide 65, which sets the general international requirements for bodies operating product certification systems. Because of this recognition, AHRI's standards and certification programs are accepted and specified all over the world.

- **American Gas Association (AGA)** The AGA, founded in 1918, is the national trade association representing energy utilities that deliver natural gas. The AGA sets standards for gas appliance operation. By conforming to AGA guidelines, manufacturers can ensure that their equipment will operate properly on gas lines provided by AGA members.
- **Canadian Standards Association (CSA)** The Canadian Standards Association is a not-for-profit membership-based association serving business, industry, government, and consumers in Canada and the global marketplace. CSA America, Inc., a division of CSA Group, is a standards development body in the United States for appliances and accessories fueled by natural gas, liquefied petroleum, and hydrogen gas. The CSA Technical Committees establish minimum construction and performance standards for gas heating equipment.

CSA also maintains testing facilities to certify gas-fired heating equipment and electrical heating and air-conditioning equipment. CSA will also do testing at the manufacturer's facility. The testing certifies that equipment meets standards set by organizations like ANSI, UL, CSA America, or the NSF. CSA Group acquired the Certification and Testing business from the AGA in 1997.

Gas furnaces and other comfort heating gas appliances tested and found to be in compliance bear the CSA Blue Star mark and are listed in the CSA Certified Product Listings. Electrical products certified by CSA International to the applicable U.S. requirements are eligible to bear the CSA U.S. mark. This mark is accepted by regulatory authorities throughout the United States and is the equivalent of the UL mark.

- **Underwriters Laboratories (UL)** UL is an independent, not-for-profit product safety certification organization that has been testing products and writing standards for safety for over a century. UL is involved in setting standards as well as testing. There are many UL standards relating to gas heating equipment.

UL gets involved in the approval and listing of heating and air-conditioning equipment, including large centrifugal machines of 100 tons and above. Local city codes and inspectors are guided by UL standards, and failure to comply with them may be costly to the manufacturer and installer. Most people are familiar with the UL mark. UL maintains

testing laboratories for certain types of products, but they often perform the necessary tests at the manufacturer's plant.

UNIT 48—SUMMARY

The three ingredients for combustion are fuel, oxygen, and heat. Complete combustion occurs when these are present in the correct quantities. The products of complete combustion of a fuel gas are carbon dioxide and water. Incomplete combustion occurs if any of the three ingredients are not present in the correct amount. Products of incomplete combustion include carbon monoxide and soot. Carbon monoxide is an extremely dangerous poisonous gas. It is odorless, tasteless, and lethal.

Gas-fired heating equipment standards are set by a number of separate agencies, including the Air Conditioning Heating and Refrigeration Institute, the American Gas Association, the American National Standards Institute, the Canadian Standards Association, the Department of Energy, the National Institute of Standards and Technology, the National Science Foundation, and Underwriters Laboratories. Testing and certifying equipment is performed by the Air Conditioning Heating and Refrigeration Institute, the Canadian Standards Association and Underwriters Laboratories. Annual Fuel Utilization Efficiency is a measure of gas furnace efficiency for the entire heating season. The minimum AFUE is 78 percent, while the most efficient furnace available rates 98 percent.

WORK ORDERS

Service Ticket 4801

Customer Complaint: Furnace Does Not Heat the House

Equipment Type: Upflow Furnace Converted from Natural Gas to LP Gas

The furnace was recently installed. It was originally manufactured for natural gas and was converted to LP by the installer. The service technician notices soot buildup on the heat exchanger. The flames are lazy and yellow, indicating incomplete combustion. There appear to be adequate combustion air openings, and they are not obstructed. The manifold pressure reading is correct. The technician checks the gas burner orifices against the manufacturer's literature and finds that they are the original orifices sized for natural gas. Since a natural gas orifice is much larger than an LP gas orifice for the same capacity, the technician concludes that the oversized orifices are delivering too much gas, leading to incomplete combustion, soot formation, and poor heating. The orifices are changed to the correct size for LP gas and the soot buildup in the heat exchanger is removed.

Service Ticket 4802

Customer Complaint: Smoke Coming out of Fireplace

Equipment Type: Upflow Gas Furnace Installed in a Hall Equipment Closet

The customer complains that if the furnace comes on when there is a fire in the fireplace, smoke starts coming out of the fireplace into the room. The technician looks in the equipment closet and finds that the combustion air grilles have been covered in plastic and taped up. The homeowner says that he noticed cold air coming in through the grilles and covered them up to keep the cold air out. The technician explains that the grilles are there to provide combustion and ventilation air for the furnace. Without them, the furnace must draw in air from the rest of the house, creating a negative pressure in the house. This is why the fireplace smoke is coming out into the room. The customer is advised that this situation could be dangerous because it could lead to the furnace producing carbon monoxide and vent gas spilling into the house. The technician removes the plastic covering the grilles and operates the furnace with a fire in the fireplace to verify that there is enough combustion air for both.

Service Ticket 4803

Customer Complaint: Furnace Comes on with a Boom!

Equipment Type: Horizontal Furnace Installed in Attic

The customer complains that the furnace sometimes lights with a loud boom. It seems to happen more in colder weather. The technician observes that the burners are noisy and that the flames seem to be lifted away from the burner outlet. The air shutter adjustment is wide open. The technician reduces the primary air by closing the shutter until the flames start at the burner instead of away from it. The technician explains that the extra primary air was making the gas-air mixture hard to light. The delayed ignition caused gas to build up, resulting in a small explosion.

Service Ticket 4804

Customer Concern: Safety of Furnace

Equipment Type: Upflow Gas Furnace Installed in Equipment Closet

A customer has purchased a new house, which is heated by a gas furnace. She has always had electric heat and is concerned about the safety of gas appliances in general and fire safety in particular. The technician agrees to do a thorough safety inspection and leaves the customer a gas safety bulletin that the local gas utility produces. The technician explains that a key factor the customer can control is the combustion and ventilation air and shows

the customer the combustion air grilles, explaining that they should not be covered up or blocked. The technician also warns against using the equipment room as a closet and recommends that the customer purchase a carbon monoxide alarm.

UNIT 48—REVIEW QUESTIONS

- Discuss the origin of natural gas.
 - List the three broad categories of fuel gases.
 - Complete this table of fuel gas characteristics.
- | Gas | Heat Capacity | Specific Gravity |
|---------|---------------|------------------|
| Methane | | |
| Ethane | | |
| Propane | | |
| Butane | | |
- What are the products of complete combustion of a hydrocarbon gas?

- What are the products of incomplete combustion of a hydrocarbon gas?
- Why are LP gases considered more hazardous than natural gas?
- Describe the two types of flames and their characteristics.
- Describe the gas combustion process as it applies to a gas furnace.
- Explain the causes of flue gas condensation and how it can be stopped.
- Explain the cause of soot formation on the heat exchanger and how it can be stopped.
- Explain how carbon monoxide is formed.
- Discuss furnace combustion air requirements.
- List agencies that establish standards for gas furnaces.
- List agencies that perform testing to verify equipment performance.
- Explain AFUE.
- What is the minimum AFUE rating for a new furnace in the United States?
- Which agencies set equipment standards and test equipment?
- Which government agencies are involved in setting equipment standards?
- What can be done to minimize the pollutants produced by a gas furnace?
- What is the purpose of excess air in furnace combustion?

UNIT 49

Gas Furnaces

OBJECTIVES

After completing this unit, you will be able to:

1. define the four categories of gas-fired furnaces.
2. list the five furnace cabinet configurations.
3. describe the operation of a standing-pilot, natural-draft furnace.
4. describe the operation of an 80 percent mid-efficiency furnace.
5. describe the operation of a 90 percent condensing furnace.
6. discuss the evolution of the heat exchanger.
7. discuss the operation of an atmospheric burner.
8. explain why furnace efficiencies jump from 80 to 90 percent.

49.1 INTRODUCTION

Gas furnaces have been one of the most common forms of heat for decades. The furnace has evolved to meet the challenge posed by rising energy costs. Furnaces today are smaller, lighter in weight, and more efficient. Understanding today's technologically advanced gas furnaces is crucial for the successful technician.

A wide variety of gas furnaces are available to meet many different applications. Factors to be considered when choosing a furnace include the fuel source, furnace location, efficiency, and venting. There are many furnaces to choose from because there are many options for each of these variables. In many cases, the contractor must choose between several possibilities because more than one type of furnace would work. Understanding all the choices will allow the installing contractor to make an informed, intelligent decision.

49.2 THE EARLY DEVELOPMENT OF HEATING SYSTEMS

The furnace of today has evolved from the old pot-bellied stove. Wood- and coal-burning stoves heated the room by a combination of convection and radiation. This type of heat was localized, and in very cold weather, people needed to huddle around the stove to stay warm. Over time, the basic principles of heating were improved to more efficiently heat the entire home.

Today's gas furnace heats by convection. Gas flames heat a heat exchanger that transfers heat to air circulating through the furnace. The heat is exchanged from the flames to the air while the combustion gasses are vented safely out through a vent. The furnace blower circulates warm air throughout the house to provide even temperatures.

Early Radiant and Convection Heat

All objects in a direct line of sight from the stove were heated by radiation. However, if something blocked the path between the object and the stove, the intermediate

object absorbed all the heat. Another problem with radiant heat is that it is uneven by nature. The amount of radiant heat transferred diminishes by the square of the distance between the source of the radiant heat and the object absorbing the heat. In simpler terms, the closer you get to the stove, the hotter you get. This means that certain areas of the room will be very warm while others will be chilly. Convection is also taking place. Cool air near the floor is heated by the stove, rises to the ceiling, loses its heat along the way, cools off, and drops back down. This does help distribute the heat, but again, somewhat unevenly. The ceiling tends to stay about 20°F warmer than the floor. Unfortunately, most of the room's occupants are closer to the floor than the ceiling.

Beginning of Ductwork

The first central furnaces were essentially pot-bellied stoves inside a metal housing. Ductwork ran from the housing to all areas of the house, producing a more even distribution of heat. Since the stove was encased in a metal jacket, all radiant heat was converted to convection heat, eliminating the problem of hot and cold spots associated with radiant heat. These early furnaces did have a few problems of their own; for instance, the ductwork was enormous since the furnace was relying on natural convection to carry the heated air through the ducts to the house. If the ductwork was not gigantic, the restriction to flow did not allow the hot air to reach the house. Also, these furnaces lost more heat than they delivered. Since heat energy was used for venting the furnace as well as for air delivery, more heat went up the chimney than was delivered into the house.

Development of Forced Convection and Sectionalized Heat Exchangers

The next logical advance was the addition of a fan to force the air over the stove, which is now called a heat exchanger. This increased efficiency by wringing more heat out of the heat exchanger. It also reduced the size of the ductwork needed to deliver the air. Although this represented quite a step forward, the pot-belly shape of the heat exchanger

Figure 49-1 Sectionalized heat exchanger.

contributed to the problem of inefficiency. A large quantity of combustion gases never touched the sides of the heat exchanger due to its large round shape. If the combustion gas does not come in contact with the heat exchanger, its heat cannot be transferred. To increase heat transfer, the barrel-type heat exchanger was squeezed, or flattened, to a rectangular box that was not very wide. This made it more difficult for flue gas to leave the heat exchanger without touching the sides, thus increasing efficiency. Typically, several of these clamshell heat exchangers were combined together, each with its own burner. This became known as a sectionalized heat exchanger (Figure 49-1).

Development of Standard and Mid-Efficiency Gas Furnaces

Furnaces remained about the same for decades and performed reliably with 60–65 percent efficiency. There was not much incentive to change them until the energy crisis of the 1970s. Suddenly, the same old furnace, which had operated economically for years, seemed to turn into a fuel-hogging monster. Of course what changed was the cost of the fuel. Changes increased furnace efficiency by about 20 percent. Through experimentation and some unfortunate experiences, an efficiency of less than 80 percent was determined to be the highest efficiency possible without condensing water out of the flue gas. Units that exceeded this efficiency had the unfortunate experience of condensing water in both the heat exchanger and the flue. This water was very corrosive due to its mild acidity, and these units often died untimely deaths of flue or heat exchanger failure.

Development of High-Efficiency Gas Furnaces

The next major increase in efficiency took advantage of the early mistakes. By intentionally designing a furnace

to condense water, efficiency could be increased. Now furnaces are available with efficiencies up to 98 percent. To do this, the point where condensation occurs has to be closely controlled, and the condensing section of the furnace is typically made of stainless steel.

49.3 GAS FURNACE TYPES

Gas heating has traditionally been mostly forced-warm-air furnaces. However, in colder climates, hydronic heating systems are often used rather than forced warm air. In these systems, hot water, rather than warm air, is circulated through the building. Hydronic systems have often been designed to utilize oil-fired boilers. This is now changing due to the increased efficiency and cleaner burn offered by gas-fired boilers. Many new installations and retrofits are using gas in lieu of oil. Gas is also a popular option for residential hot-water heaters, providing an almost continuous supply of hot water without the need for a hot-water holding tank.

Gas Forced Warm Air

Gas forced-warm-air furnaces are composed of two main sections: the heat exchanger compartment and the blower compartment. The arrangement of these two sections determines the general style of the furnace. Regardless of the style, the air always travels through the blower compartment first, before going to the heat exchanger. The reason is fairly simple: the fan motor would overheat otherwise. Furnaces can be categorized into five styles: upflow, lowboy, downflow or counterflow, horizontal, and multiposition.

For the most part, airflow through the furnace gives it its name. Air travels up in an upflow furnace, down in a downflow furnace, and horizontally in a horizontal furnace.

The upflow furnace (Figure 49-2) is most popular. Its narrow width and depth allow for location in first-floor closets and/or utility rooms. It can still be used in most basement applications for heating only or with cooling coils where headroom space permits. Blowers are usually directly driven by multispeed motors or variable speed electronically commutated motors (ECM). Return air can be either from the sides or from the bottom.

The counterflow or downflow furnace (Figure 49-3) is similar in design and style to the upflow, except that the air intake and fan are at the top and the air discharge is at the bottom. These are widely used where duct systems are set in concrete or in a crawlspace beneath the floor. A fireproof base is required when the furnace is installed on a combustible floor. An extra safety limit control in the fan compartment is required.

Horizontal furnaces are installed in low areas such as crawlspaces, attics, or partial basements (Figure 49-4). They require no floor space. Intake air enters at one end and is discharged out the other end. On older-style furnaces, burners are usually field changeable for left-hand or right-hand application.

Lowboy furnaces are built low in height to accommodate low ceilings. These furnaces are approximately 4 ft high, providing for easy installation in a low-ceiling-height

Figure 49-2 Upflow highboy furnace.

Figure 49-3 Counterflow furnace.

Figure 49-4 Horizontal furnace.

basement. Lowboy furnaces have two sections side by side, like horizontal furnaces. But the air goes in the top of the furnace, makes a 180° turn as it goes through the furnace, and then leaves out the top of the furnace. Blowers are commonly belt driven. Many of these furnaces are sold for retrofitting older homes.

The installation technician can configure the fifth style, the multiposition furnace, on the job site to be an upflow, horizontal, and/or downflow furnace. The introduction of the multiposition furnace has allowed manufacturers and contractors to reduce the number of furnaces they must keep in inventory to meet local demand. The vent typically needs to be configured for the installation. Figure 49-5 shows a vent configured for upflow, downflow, and horizontal installation. Typical installations of the horizontal, counterflow, and upflow furnaces are shown in Figure 49-6.

Gas-Fired Boilers

Gas-fired boilers circulate hot water through baseboard heaters or radiant floor piping. In addition to the boiler,

(a)

(b)

Figure 49-5 Multiposition furnace.

Figure 49-6 Composite diagram of three types of furnace installations:

(1) attic installation of a horizontal furnace;
 (2) first-floor installation of a counterflow furnace;
 (3) basement installation of a lowboy furnace.

these systems include a number of additional components for the water loop. These include water-circulating pumps, an expansion tank, and water flow control valves. There will also be a heat exchanger to heat the water. A gas-fired hydronic heating system and its small plate-type heat exchanger are shown in Figure 49-7.

49.4 GAS FURNACE COMPONENTS: MANIFOLD

The purpose of the manifold is to supply gas to all the burners. The manifold is usually a length of pipe connected to the gas valve on one end and closed on the other end (Figure 49-8). There is a small plug, called a spud, along the manifold at each burner inlet (Figure 49-9) that threads into the manifold. Occasionally the manifold has a threaded plug that can be removed to check the manifold pressure.

49.5 GAS FURNACE COMPONENTS: ORIFICE

An orifice is a precisely drilled hole that meters the correct amount of gas into the burner. The orifice is drilled into a spud (Figure 49-10). Since the orifice size is what really matters, most people refer to the spud as the orifice. The specified sizes are very small and they must be drilled accurately. A slightly larger hole lets in too much gas and overfires the burner. A hole that is not drilled straight can cause even more problems.

A venturi is a narrow passage located just after the orifice and is used on atmospheric burners to draw in air for combustion. The venturi is the initial portion of the burner that is shaped like an hourglass. As gas and air are drawn through it they swirl, like water going down a toilet. The swirling mixes the gas and air. The space between the orifice and venturi has to be open so that primary air can

(a)

(b)

(c)

Figure 49-7 (a) Gas hydronic system; (b) gas hydronic furnace; (c) small plate-type heat exchanger is located inside the furnace.

Figure 49-8 Gas manifold shown with burners located directly underneath the blower.

Figure 49-9 Gas manifold.

Figure 49-10 Spud with orifice number.

be injected by the jet action of the gas emitting from the orifice. If the gas stream does not aim straight inward, it may hit the side of the venturi, or worse, the gas stream may miss the venturi altogether. This causes poor ignition and even explosions. While it is not impossible for a factory orifice to be drilled incorrectly, dirt, dust, or other debris is more likely the cause of the gas stream being deflected.

Orifice Size Determination

The size of the orifice is determined by three factors: the specific gravity of the gas, the heat content of the gas, and the required BTU/hr rating of the burner. The first two factors, specific gravity and heat content, are generally set by the gas type, which is usually either natural gas or propane. The unit's BTU/hr rating divided by the number of burners determines the burner BTU/hr rating. For example: on a 40,000 BTU/hr furnace with a single burner, the orifice BTU/hr rating would be 40,000 BTU/hr. However, if the same 40,000 BTU/hr furnace had two burners, each burner orifice would be rated at 20,000 BTU/hr. Once you know what type of gas the burner uses and the BTU/hr required for each burner, you could look up the orifice size in an orifice chart (Table 49-1).

49.6 GAS FURNACE COMPONENTS: BURNERS

The purpose of the gas burner is to properly mix the primary air and gas and to deliver this mixture in a manner that can be easily ignited and burned. There are two general types of burners: the atmospheric burner and the power burner. The atmospheric burner draws its air in from the surrounding atmosphere and requires air both at the point of gas entry and at the point of combustion. Power burners, on the other hand, normally get all their air at the point of gas entry. A power burner also draws its air from the surrounding atmosphere, but a blower forces it in mechanically. Many power burners pressurize both the air and the gas and are able to burn large quantities of gas quickly. The basic residential burner is the atmospheric burner. Even induced- and forced-draft units normally use atmospheric burners, even though the "draft" through them is mechanically produced.

Atmospheric Burners

The burner generally slides onto the spud, with the spud located in the middle of the burner face. The primary air openings are located all around it. In older furnaces, these air openings were fitted with adjustable shutters to control primary air entering the burner (Figure 49-11). Air shutters are no longer used on modern burners.

Figure 49-11 Primary air shutter.

Table 49-1 Gas Orifice Capacity in BTU/hr

Drill	Size	Natural Gas 3.5 in wc BTU/hr	Propane 11 in wc BTU/hr
70	.0280	1,991	5,476

Figure 49-12 In-shot atmospheric gas burner.

The gas shoots out of the orifice in a small, quick stream, which creates a negative pressure around it and draws in primary air through the primary air openings. The burner is shaped like an hourglass on the end. It has a large diameter at the face where the gas and air enter, a small diameter a short distance away, and returns to a large diameter at the burner's main body. This shape, called a venturi, causes the gas and air to swirl as they pass through the constricted opening, mixing them together (Figure 49-12). The orifice, primary air shutters, and venturi are crucially important because together they are responsible for mixing the gas and air in the correct proportions for complete combustion. Next, the gas travels through the venturi into the main burner body. Here, the gas-air mixture slows down and expands to fill the chamber. The mixture leaves through the burner ports.

There are several styles of ports, including in-shot (one large hole), drilled port (several small holes drilled in the burner), and slotted (ribbon). Drilled-port burners produce lots of small, distinct flames (Figure 49-13). These are

Figure 49-13 Drilled-port burners produce small, distinct flames.

Figure 49-14 Slotted atmospheric burner.

Figure 49-15 Slotted burners can produce long, thin, ribbon flames.

usually quieter but less efficient than in-shot burners. Slotted-port burners are usually made of stamped sheet metal, and the slots are larger than the holes in a drilled-port burner (Figure 49-14). Ribbon burners consist of several slots, which run the length of the burner. These produce long, thin, ribbon flames (Figure 49-15).

Virtually all furnaces today use in-shot burners because of their efficiency and because the flame from an in-shot burner fits the narrow heat exchangers used today (Figure 49-16). In-shot burners are generally the most efficient type of atmospheric burners, but they are also the noisiest. In-shot burners produce a flame like a jet or rocket tail.

Regardless of the burner style, a good flame should have a bright blue inner cone surrounded by a darker blue outer cone. There should be no yellow in the flame; yellow indicates either too little air or too much gas in the mixture. This should not be confused with intermittent orange flashes often caused by dust particles passing through the burner.

Power Burners

The other basic type of gas burner is the power burner. Power gas burners are seldom used on residential equipment, although a few units have used power burners. Power burners use a fan to force both the air and the gas into the combustion area. The air and gas can be mixed

(a)

(b)

Figure 49-16 (a) In-shot atmospheric gas burner; (b) in-shot atmospheric gas burner, manifold, and spuds.

in the fan itself or after the fan inside a tube with angular vanes to create a vortex action that mixes the air and gas. Generally, power burners are ignited by spark igniters or glow coils. Using power burners can achieve higher burning efficiencies than atmospheric because they have better control over the fuel-air ratio. Power burners are used on commercial multi-fuel furnaces. Nongaseous fuels, such as oil, require power burners for operation. The use of a power burner can make changeover from gas to oil easier.

49.7 GAS FURNACE COMPONENTS: HEAT EXCHANGERS

The job of the heat exchanger is to separate the combustion process from the air being heated and, as its name implies, exchange the heat from the combustion process to the air being circulated over the heat exchanger. To perform the job of gas separation, a heat exchanger needs only to be an airtight vessel with a hole in the bottom for the burners and one at the top for the flue gas to escape. As long as there are

no holes in between these two openings, there is no problem. The second job, efficient heat transfer, is not as simple.

The earliest heat exchangers were basically barrels with a hole in the bottom and a hole in the top. They were adequate for gas separation but were rather inefficient heat-transfer apparatuses. Large quantities of the relatively unrestricted flue gas found its way up the vent without ever contacting the surface of the heat exchanger. This translates into lost heat.

Sectionalized Heat Exchangers

By flattening the heat exchanger, more resistance to flow was created, which forced more of the combustion products to touch the walls of the heat exchanger, increasing efficiency. Several of these flattened heat exchangers were used together to create one unit. These are commonly called sectionalized heat exchangers because they are built in sections (Figure 49-17). The vent opening on sectionalized exchangers is on the side at the top. Flue baffles were added at the top of the sectionalized heat exchangers (Figure 49-18). The baffles restrict the flow of combustion

Figure 49-17 Sectionalized heat exchanger.

Figure 49-18 Heat exchanger baffles.

Figure 49-19 Serpentine heat exchanger section.

gases at a constriction near the top of the heat exchanger. This forces them to stay in the heat exchanger longer, thus increasing heat transfer.

Serpentine Heat Exchangers

This concept was taken further with serpentine heat exchangers. The serpentine path and the narrow width helped squeeze more heat out of the combustion gas (Figure 49-19). These features also required an induced-draft fan to draw the combustion gases through the heat exchanger. A fan pressure-breaking baffle was installed at the discharge of the induced-draft blower, making the vent pressure negative so that the furnace could be vented with standard type B vent. Furnace manufacturers began to use automotive exhaust tubing as the heat exchanger. By bending tailpipe material in a serpentine configuration, they managed to produce a heat exchanger that gave them 80 percent efficiency yet used considerably less material and energy to produce.

The most common type of heat exchanger is made from two formed or stamped steel sheets welded together (Figure 49-20). These sections are welded together and form a header at the top and bottom. The number of

Figure 49-20 Typical furnace heat exchanger.

sections depends on the capacity of the furnace. The contours of the heat exchanger sections create turbulence to increase heat transfer.

Recuperative Coils

To get into the 90+ percent range, you must condense. Most 90 percent furnaces are an 80 percent furnace with a stainless steel recuperative condensing coil. Most of these recuperative coils are built like a refrigeration coil, only from stainless steel. Some recuperative coils are just smaller stainless steel serpentine heat exchangers. Recuperative coils are installed ahead of the main heat exchanger in the airstream. Obviously, any unit employing such a coil must also provide a drain for the furnace.

So far, the experience with this approach has been very good. If you plan ahead for condensation to take place, then it ceases to be a problem. These units have another common characteristic: PVC positive pressure vents. The flue gas leaving a 90 percent efficient furnace feels warm and wet to the hand. PVC can handle the temperature easily. The positive pressure is no problem as long as PVC is used because it is relatively simple to ensure a leakproof PVC vent. The positive pressure also allows more flexibility in vent location and design since the flue gas is being pushed out, not floating out. Most major manufacturers now offer a 90+ percent condensing furnace as part of their product line, and installation practices are similar from one to another.

Burner Location

Traditionally, burners were located at the bottom of the heat exchanger and flue gases escaped out the top because the furnace relied on natural convection to move the flue gas through the heat exchanger. The addition of the induced-draft blower made it possible to have the flames at the top of the heat exchanger and the exhaust gases leaving the bottom of the heat exchanger. The counterflow process, where the combustion gas moves in the opposite direction from the air, is more efficient. Many manufacturers use the counterflow heat exchanger design in their 90 percent efficiency models.

Temperature Rise

A key operating characteristic of any furnace is its temperature rise. Manufacturers give the acceptable temperature rise range on the data plates of their units. For a standard furnace, the temperature rise range is usually 40 to 70°F. However, the exact range will change depending on the unit's capacity and airflow. The range will always be listed on the unit data plate. For example, a furnace with a temperature rise of 40 to 70°F and an entering air temperature of 75°F should have a leaving air temperature of 115 to 145°F. The higher the efficiency of the furnace, generally, the lower the temperature rise. To increase efficiency, increase the airflow through the unit compared to a standard furnace with the same BTU/hr rating. Thus, since there is more air to absorb the heat, more heat will be absorbed. However, that also means that less heat will go into each cubic foot of air, so the temperature rise of the air will be less. High-efficiency furnaces normally have a temperature rise of between 25°F and 65°F.

49.8 CATEGORY RATINGS AND EFFICIENCIES OF GAS FURNACES

Furnace manufacturers mostly offer two types of furnaces:

- Mid-efficiency category I fan assisted
- High-efficiency category IV condensing-type furnace

The mid-efficiency furnaces meet the minimum requirement of 78 percent AFUE (annual fuel utilization efficiency) and have a flue gas temperature at least 140°F above the dew point of the flue gas. The high-efficiency furnaces have flue gas temperatures below the dew point and permit condensation within the furnace to pick up the extra latent heat. In addition to these, there are standard low-efficiency furnaces, but they are no longer being manufactured. Even so, many of the earlier models of standard furnaces are still in operation and will require service. These utilize natural-draft venting, and most use standing pilots.

Standard Low-Efficiency Gas Furnaces

Lower-efficiency gas furnaces are the older units now in the field, all of which were manufactured prior to 1992. Since so many are in use and will require service for some time, this section describes them and indicates some differences from the newer designs.

A cross-sectional diagram for one of these units is shown in Figure 49-21. One distinctive characteristic of the older design is the convection flow of combustion gases from the burner, past the heat exchanger, and into the vent (Figure 49-22). This convection action of the flue gases requires a different type of venting as compared to newer, more efficient units that use fan assist.

Newer standard gas furnace burners like the one shown in Figure 49-23 use electronic igniters, while some of the older units used a standing, continuous-flame gas pilot. This pilot consumes a small amount of gas continuously. Along with the pilot is a runner attached to the main burner. The purpose of the runner is to carry the gas flame from the pilot to all of the burners. The pilot flame impinges on the thermocouple about ½ in, which provides a safety arrangement for turning off the gas if the flame is ever extinguished (Figure 49-24).

Figure 49-22 Standard low-efficiency gas furnace.

Figure 49-23 Standard low-efficiency gas furnace burners that use electronic ignition.

Category Ratings

A modern gas furnace's operational characteristics will place it into one of four categories based on its flue gas temperature and pressure.

- **Category I** An appliance that operates with a nonpositive vent static pressure and with a vent gas temperature greater than 140°F above the flue-gas dew point, which avoids excessive condensate production in the vent
- **Category II** An appliance that operates with a nonpositive vent static pressure and with a vent gas temperature less than 140°F above the flue-gas dew point, which may cause excessive condensate production in the vent
- **Category III** An appliance that operates with a positive vent static pressure and with a vent gas

(a)

(b)

Figure 49-24 (a) Standing pilot and flame rod with burner flame off; (b) standing pilot with burner flame on.

temperature greater than 140°F above the flue gas dew point, which avoids excessive condensate production in the vent; however, the positive-pressure vent requires a sealed vent system

- **Category IV** An appliance that operates with a positive vent static pressure and with a vent gas temperature less than 140°F above the flue-gas dew point, which may cause excessive condensate production in the vent

Category I Furnaces

Category I furnaces can be divided into natural draft and fan assisted. Many furnaces sold today are Category I, fan assisted. The fan on most 80 percent furnaces does not produce a positive vent pressure because it is sized just large

enough to overcome the resistance of the heat exchanger and because the temperature of the flue gas makes it lighter than air. A benefit to fan-assisted furnaces is that the heat exchanger operates in a negative pressure. This ensures added safety to the consumer because if a hole develops in the heat exchanger, the surrounding air rushes into the heat exchanger, preventing harmful flue gases from escaping into the occupied space.

Category II and III Furnaces

Category II and Category III furnaces are rare. Both of these require special vent materials, making their installation more costly. A special high-temperature plastic vent material was developed for use with Category II and III furnaces. This venting material is no longer manufactured because of high failure rates and the resulting legal action.

Category IV Furnaces

Category IV furnaces are also common; they are the 90 percent condensing furnaces. Since the flue gas is relatively cool, PVC can be used as a vent material. PVC is easy to seal airtight, and water will not bother it.

49.9 MID-EFFICIENCY FURNACES (80 PERCENT AFUE)

Furnace manufacturers achieve an efficiency of 80 percent by eliminating the pilot light, improving heat exchanger efficiency, and adding an induced-draft blower.

The internal components of a mid-efficiency furnace include the following:

- The inducer blower assembly, with an induced-draft blower to draw the flue gases through the heat exchanger and to the vent (Figure 49-25). The inducer motor draws the exact amount of air needed through the combustion exchanger. The assembly is resiliently mounted to provide quiet operation.
- The pressure switch, which proves that the inducer fan is operating before the fuel can be ignited.
- The gas control valve, which delivers the fuel gas into the burner. The gas valve opens slowly to provide a controlled ignition. It also provides for 100 percent shutoff to ensure safe operation.
- The burner assembly, which provides for proper mixing of fuel and air and ignites the fuel.
- The blower door safety switch, which disconnects the power supply to the unit whenever the front access panel is removed.
- The control box, which houses controls, including a microprocessor board that controls most furnace operations and functions. It provides a blower delay on startup and shutdown and monitors furnace performance. The technician can use this self-testing feature to identify a major component failure. The control board will check itself, then the inducer, silicon carbide ignition, low- and high-speed blower operation, and humidifier connections. Control boards often include a low-amperage fuse that protects the

Figure 49-25 An inducer blower used to force the combustion gases through the furnace.

transformer and control board. The boards may also include an LED status indicator light.

- The air filter retainer, which holds the air filter.
- The air filter, which is either the replaceable type or an optional electronic filter that can be installed in the return-air opening.
- The wraparound casing, which is a one-piece with seamless construction.
- The heat exchanger, which transfers the heat of combustion to the air-distribution system.
- The blower and blower motor, which force the air over the external surface of the heat exchanger to pick up the heat for delivery to the space. The motor is a direct-drive multiple-speed type.

TECH TIP

Some early Honeywell igniter controllers have an internal fuse. This fuse is not replaceable. If the leads are accidentally shorted, it will blow and the entire control board must be replaced. When working with any electronic device, be certain not to accidentally short any wires together for fear of damaging the component.

When the first 80 percent furnaces were being introduced, there were still many furnaces around with efficiencies in the 50–60 percent range. The 80 percent furnaces represented a midpoint in both efficiency and cost between

the traditional standing-pilot, natural-draft furnace and the higher 90 percent condensing furnaces. Today, the 80 percent furnaces represent most manufacturers' bottom line. The minimum efficiency is 78 percent.

49.10 PRODUCT DATA (80 PERCENT AFUE FURNACE)

Following the information supplied by the manufacturer about the product during installation is important. The technician needs to check the installation, either at the time of startup or whenever a service problem arises to determine that the product has been properly installed. Some of this information appears on the nameplate, but not all of it may be listed. Data that is particularly important include:

- Minimum gas-line pressure
- Maximum gas-line pressure
- Manifold gas pressure
- Temperature rise
- Electrical characteristics
- Input capacity
- Output capacity

Although these units are primarily designed for heating, a number of accessories can be added, such as a cooling coil installed in the supply plenum, a humidifier installed on the supply duct, and an electronic air cleaner installed at the return-air entrance to the unit.

CAUTION

In most places, it is against code to install an air-conditioning coil in the return-air plenum of a furnace. If a coil were to be installed in the return-air plenum, the heat exchanger would be cooled below the dew point during the air-conditioning season. The resulting condensate would quickly rust out the furnace and heat exchanger.

The 80 percent AFUE units usually have output ranges of 35,000 to 124,000 BTU/hr. On larger jobs it may be necessary to install two of them linked together in a configuration called twinning. Twinning kits are available for field linking. A number of parts are required, and the manufacturer's instructions must be carefully followed to coordinate the two systems. When twinned, it is imperative that both blower motors energize simultaneously. Also, twinned furnaces typically result in at least a 10 percent loss of combined air volume (in CFM).

TECH TIP

When working on a customer's furnace equipment, avoid tracking grease and/or dirt into their home after the work is complete. If you are in a basement and must exit the house across a clean floor or rug, remove your shoes or cover them with paper shoe covers. You must never leave any tracks behind. A little time spent ensuring your footwear is clean will help ensure customer satisfaction.

49.11 GAS HIGH-EFFICIENCY FURNACES (90+ PERCENT AFUE)

High-efficiency or condensing-type gas furnaces are rated at 90 percent AFUE or better. They differ from the 80 percent AFUE mid-efficiency furnaces in that an extra heat exchanger (secondary heat exchanger) is added to extract more heat from the flue gases. This additional surface causes the moisture in the flue gas to condense. Additional heat is obtained by further lowering the temperature of the flue gas and picking up the heat rejected by the condensing moisture. Notice in Figure 49-26 that the burners are at the top, where the hot air is leaving.

This construction reduces the volume and temperature of the flue gas, making it possible to use smaller vent pipes and simplify venting arrangements. Since the temperature of the flue gas is lower, PVC vent piping can be used and vent outlets can be run to the side of a building, if more convenient.

A condensate line is required to dispose of the condensed water. This needs to be run to the suitable drain. The condensate usually contains some contaminants. Local

codes need to be examined to determine the possible need for a condensate-neutralizer kit.

49.12 PRODUCT DATA (90+ PERCENT AFUE FURNACES)

90+ percent AFUE furnace product data cover information similar to that of the 80 percent AFUE models, but with a few additions. Since these are condensing-type furnaces, a drain for the condensate is needed.

Many high-efficiency furnaces have provisions for piping combustion air to the furnace from the outside (Figure 49-27). This keeps the furnace from drawing air out of the house. Piping in outside combustion air also keeps household chemicals that are in the air inside the house out of the furnace. Piping in combustion air means that two PVC lines are required: one for the combustion air and one for the vent gases (Figure 49-28).

(a)

(b)

Figure 49-26 (a) High-efficiency furnace with burners located at the top where the hot air is leaving; (b) sealed combustion chamber with inspection port.

Figure 49-27 Gas furnace with piping for combustion air.

Figure 49-28 When possible, install the combustion air and vent pipes through the side wall of a building, as this method of side venting reduces the possibility of roof leaks.

Table 49-2 A Typical Table Giving Maximum Allowable Vent Pipe Length (ft)

Pipe Diameter (in)	Number of 90° Elbows					
	1	2	3	4	5	6
1½	70	70	65	60	60	55
2	70	70	70	70	70	70

Table 49-3 Limit on the Length of an Exposed Insulated Vent Pipe (ft) in an Unheated Area

Winter Temperature (°F)	Pipe Diameter (in)	Insulation Thickness (in)				
		0	3⁄8	½	¾	1
20	1½	31	56	63	70	70
0	1½	16	34	39	47	54
–20	1½	9	23	27	34	39

Some direct-vent furnaces use a concentric vent. This allows both vent pipe and combustion air pipe to terminate through a single exit in the roof or sidewall. One pipe runs inside the other, permitting venting through the inner pipe and combustion air to be drawn through the outer pipe.

The positive pressure in the vent pipe created by the draft-inducer fan in 90 percent furnaces is not very strong. Long runs or several elbows can reduce flow through the vent. This can lead to the furnace shutting off on the draft safety switch. As an example, Table 49-2 shows the maximum vent length and number of elbows allowable for one type of a 90 percent condensing furnace. When the vent pipe is exposed to temperatures below freezing, such as when it passes through an unheated space or when a chimney is used as a raceway, the pipe must be insulated with Armaflex-type insulation. There is a limit on the length of an exposed insulated vent pipe (ft) in an unheated area, as shown in Table 49-3. Vent piping should not have any traps or low places where water can collect and form restrictions. In general, the vent should slope back toward the furnace, where provisions are made for collecting and disposing of the condensate. It is possible to install the vent horizontally if the manufacturer’s instructions are followed. Typical installations of units and venting arrangements are shown in Figures 49-29 and 49-30.

These values are for altitudes of 0 to 2,000 ft above sea level, using either two separate pipes or a 2-in concentric vent.

Figure 49-29 Side-venting condensing gas furnace.

SAFETY TIP

Because vent sizing is so important, you must check with the equipment manufacturer and with local and state regulations before designing and installing furnace vent piping.

49.13 COMBUSTION CONDENSATE PIPING

The condensate drain line should be trapped. However, many furnaces have a condensate trap built into the furnace, eliminating the need for another trap. Some condensing

Figure 49-30 Top-venting condensing gas furnace.

furnaces require an external trap in the condensate drain line. The field drain connection is typically sized for $\frac{1}{2}$ -in CPVC or PVC. The condensate drain should be run with schedule 40 PVC or CPVC.

Not all condensate pumps are approved for installation on condensing furnaces because furnace condensate is mildly acidic, typically in the pH range of 3.2 to 4.5. When a condensate pump is required, select a pump that is approved for condensing furnace applications. Ideally, the pump should also have an overflow switch to avoid condensate spillage in the case of pump failure or a stopped drain.

Due to corrosive nature of this condensate, a condensate pH-neutralizing filter may be desired. These filters are typically PVC canisters filled with limestone. Check with local authorities to determine if a pH neutralizer is required.

Do not normally combine a furnace condensate drain and evaporator condensate drain. Pressure produced in an upflow coil plenum can pressurize the drain and the secondary heat exchanger in the furnace. This stops the furnace from draining, pressurizes the heat exchanger, and causes the furnace to lock out on its pressure-switch safety.

If the furnace, air-conditioner, and humidifier drains are combined and drained together, then the air-conditioner drain must have an external, field-supplied trap prior to the

furnace drain connection. The drain should be $\frac{3}{4}$ -in PVC or CPVC when combining with the air-conditioner drain. When terminating the drain inside, it should be run into an open or vented drain as close to the respective equipment as possible. Outdoor draining of the furnace is permissible if allowed by local codes. Caution should be taken in cold climates because low temperatures may freeze the drainpipe and prohibit draining.

When condensing furnaces are used in an attic application or over a finished ceiling, local codes may require a drain pan under the entire furnace to prevent damage to the ceiling in the event of a plugged drain. The auxiliary drain should terminate in an obvious location so that any condensate from it will be noticed.

49.14 VARIABLE-CAPACITY FURNACES

Two ways manufacturers have to offer a premium furnace are by offering two-stage combustion and ECM blower motors. One of the most wasteful periods of a furnace operation cycle is the warm-up time when the burners are firing and the fan is not on. Increased cycling leads to decreased efficiency. The furnace run time can be extended and the cycling reduced by using a two-stage gas valve. On low fire, the furnace capacity is approximately half of the furnace's full capacity. This allows the furnace to operate for longer periods of time in milder weather. When the full capacity is needed, high fire can still deliver the full furnace capacity. On low fire, the gas valve operates at a lower manifold pressure so not as much gas goes into the burners. On high fire, the manifold pressure is normal, providing full capacity. Two-stage furnaces are available in both 80 percent and 90 percent AFUE ratings.

Customers are looking for more than just efficient gas usage; they want electrical savings also. ECM blower motors are more efficient than the standard PSC blowers and offer many operational advantages. ECM blowers are a natural pairing for furnaces with two-stage operation. ECM blower motors can deliver the correct amount of airflow for both low-fire and high-fire operation and consume less electricity as well. Some manufacturers now produce full modulating furnaces that effectively provide for upwards of one hundred stages of capacity.

49.15 PRODUCT DATA (VARIABLE-CAPACITY FURNACES)

The distinguishing features of variable capacity furnaces are the components that allow for two firing rates, including two-stage gas valves, two-speed induced-draft fan, two-draft proving switches, and the use of a two-stage thermostat.

The two-stage gas valve is the primary component that makes these furnaces possible. It has adjustments for both the low-fire and high-fire manifold pressures. Common settings for manifold pressures are 3.2 in wc to 3.8 in wc for high fire, and 1.4 in wc to 1.7 in wc for low fire. The BTU value of the gas and the altitude of the installation will determine the correct manifold pressures for any particular installation.

Figure 49-31 Two-stage thermostat sub-base.

SAFETY TIP

Always follow the manufacturer's installation instructions when adjusting a furnace firing rate for high altitude. Manufacturers specify the burner orifices and manifold pressure for different altitude applications.

The induced-draft fan motor must also move less air for low fire than it does for high fire. This can be done using a multispeed PSC motor or by using an ECM motor. Two draft-proving switches are also necessary—one for low fire and one for high fire.

Finally, a two-stage thermostat is needed to control the furnace. The thermostat should have both W1 and W2 terminals (Figure 49-31). A heat pump thermostat will not work. Some systems also have provisions for using an outdoor thermostat to control when the furnace runs in low fire and when it runs in high fire.

UNIT 49—SUMMARY

Furnaces can be grouped many different ways: by their fuel source, venting characteristics, cabinet configuration, and efficiency. Most manufacturers offer two types

of gas furnaces: 80 percent efficient Category I fan assisted, and 90 percent efficient Category IV condensing furnaces. All furnaces made today use an induced-draft combustion blower and an improved efficiency heat exchanger. High-efficiency furnaces achieve 90+ percent efficiencies by condensing water from the flue gas using a recuperative heat exchanger made of stainless steel. Medium-efficiency furnaces are vented with type B vent, while high-efficiency furnaces are vented with PVC. Some high-efficiency furnaces require the combustion air to be piped in from outside.

WORK ORDERS

Service Ticket 4901

Customer Request: Old Furnace Needs Replacement
Equipment Type: Natural-Draft Horizontal Gas Furnace

A sales consultant is contacted by a customer and is asked for recommendations to replace an old natural-draft horizontal gas furnace installed in a crawlspace. The first step in this process is for the sales consultant to visit the residence and determine what will work best. The structure of the building and the heating load requirements need to be taken into account.

The consultant observes that the old furnace is vented into a masonry chimney. This will lead to additional costs because an 80 percent furnace cannot be vented into the masonry chimney without installing a liner. The customer asks if there are any other alternatives to consider. The consultant does have an option. The money that would be spent on the liner may be invested in a 90 percent furnace, which can be vented with PVC out the side of the crawlspace. This will not only save on fuel bills, but it will also eliminate the need for lining the existing chimney.

Service Ticket 4902

Customer Complaint: Old Furnace Needs Replacement

Equipment Type: Natural-Draft Upflow Gas Furnace

A customer would like to replace an old natural-draft upflow gas furnace installed in a basement. After visiting the residence, the sales representative explains to the customer that an 80 percent Category I furnace can use the old venting system.

However, after careful consideration, it is noted that the old furnace used a 7-in vent and the new 80 percent model only needs a 4-in vent. The increased size of the vent could lead to condensation and premature failure of the furnace. The consultant explains to the customer that although the new 80 percent model will work just fine, the vent system must also be replaced with the furnace.

Service Ticket 4903**Customer Request: New Home Furnace Installation****Equipment Type: 80 Percent Two-Stage Furnace**

A customer wants to install a 90 percent condensing furnace in his new home, but the only place available is in the attic. The house is located in a very cold climate and the attic frequently drops below freezing in the winter. In this type of installation, the furnace condensate could freeze, especially if the system is operated and then shut off for several hours.

The sales consultant visits the residence and spends some time discussing the possibilities with the customer. Although a 90 percent condensing furnace may save in heating costs, the potential for freeze-up is problematic. To avoid this, the furnace would need to run more frequently, and there would still be no guarantee that the condensate would not freeze in the cold attic. The sales consultant instead recommends an 80 percent two-stage furnace with an ECM fan motor. In the long run, this would be the best alternative for the customer.

Service Ticket 4904**Customer Request: New Installation in Closet****Equipment: 90 Percent Counterflow Furnace**

A sales consultant is asked for recommendations for a counterflow furnace to be installed in a closet in a new home. The design calls for the ductwork to be located within the house's concrete slab. The homeowner asks the sales consultant if this type of design is acceptable.

The sales consultant explains that with this type of installation there could be concerns regarding the proper supply of combustion air. This is mainly because the furnace will be located in the living space. Provided the design criteria and after consulting with the customer, the sales consultant recommends a 90 percent furnace with combustion air piped in from the outside. This will provide sufficient air for operation of the furnace and will not take away from any air in the living space.

Service Ticket 4905**Customer Request: New Furnace Relocation****Equipment Type: Upflow/Horizontal Flow Furnace**

A homeowner has decided to install a furnace in the basement of his house. He purchases a furnace on sale from Furnace Mart and begins to install the furnace in the basement. After the job gets started, his wife inspects the furnace in the basement and does not like its

location. She would prefer that the furnace be installed in the attic like the neighbor's.

The homeowner explains to his wife that he has already purchased the furnace and it is designed to be installed in the upflow position. His wife tells him to call a professional and find out if anything else can be done. At first the homeowner is reluctant but then after looking over the system he decides that maybe his wife is right. He is relieved after talking to a technician. It appears that the attic installation will work out just fine and the furnace he purchased can be adapted for this configuration. Although it costs the homeowner more money than if he installed the furnace himself, he feels reassured that the job was done professionally and with every safety requirement in mind.

UNIT 49—REVIEW QUESTIONS

1. List the four categories of gas-fired furnaces based on flue-gas temperature and pressure.
2. Explain the difference between a Category I furnace and a Category IV furnace.
3. List the five furnace cabinet configurations.
4. Why are standing-pilot natural-draft furnaces no longer manufactured?
5. What changes were made in furnace design to achieve 80 percent efficiency?
6. What is the difference between an 80 percent efficient furnace and a 90 percent efficient furnace?
7. Discuss the evolution of the heat exchanger.
8. Discuss the operation of an atmospheric burner.
9. Explain why furnace efficiencies jump from 80 percent to 90 percent.
10. What is the purpose of the orifice?
11. Why is it not a good idea to drill out orifices in the field?
12. What components are needed for a furnace to operate as a two-stage furnace?
13. Why are some condensate pumps not approved for furnace condensate?
14. Can the furnace drain and the air-conditioning drain be run with a common drain?
15. List the different types of gas burners.
16. Why do most furnaces today use burners?
17. What is the temperature rise of a furnace?
18. What part of the furnace does the air travel through first in all furnace cabinet configurations?
19. Why should technicians be familiar with standing-pilot, natural-draft furnaces, since they are no longer manufactured?
20. Why are draft-inducer fans necessary in today's furnaces?

UNIT 50

Gas Furnace Controls

OBJECTIVES

After completing this unit, you will be able to:

1. identify and name the different types of control components.
2. describe the operation of flame safety devices.
3. explain the function of gas pilots.
4. explain the operation of a direct-spark ignition system.
5. describe how gas valves operate with thermostat and limit controls.
6. determine the maximum length of wire run to limit voltage drop.
7. explain the operation of a control circuit.
8. wire a control circuit.

50.1 INTRODUCTION

Controls can be used to accomplish a number of different tasks in a system. Most commonly they will function to operate a system within prescribed limits, such as a thermostat control that starts a furnace when the temperature falls below the set point. Controls can also serve as safety devices—for example, to shut down a furnace if there is a flame failure. They can be designed with remote operation for convenience purposes, making it easier for the customer to change the operational settings. In addition, controls can be designed to cycle the furnace on and off in such a manner as to operate the most efficiently.

50.2 TYPES OF CONTROL SYSTEMS

Control systems will vary depending on the furnace type and design. Gas warm-air furnaces will have slightly different controls than gas hydronic furnaces. There are also differences between single-stage, multistage, and variable-speed furnaces.

Single-Stage Gas Furnaces

A single-stage gas warm-air furnace will have a very simple type of control system. A thermostat located in the space to be heated is one of the major components. When the thermostat calls for heat, the furnace will start. The fan switch will turn on the blower at a set temperature or time-delay setting. There are also safety controls such as the limit switch. This prevents the furnace from overheating. Gas valves are also designed for safety and will close to stop the gas flow upon an unexpected flame out.

The control components for a single-stage furnace can be very basic, such as a simple snap-action thermostat, some basic relays, a fan switch, a limit switch, and a combination gas valve. The major drawback to this type of furnace is that the heat output is constant. This means that the furnace is either on or off. To keep the building at a constant temperature, the furnace will continually cycle.

Multistage Gas Furnaces

Multistage gas furnaces are more efficient. They will produce heat at two or more different rates. Two-stage gas furnaces are a very common type of multistage furnace. As an example, there will be a high and a low setting. When less heat is required, the furnace will operate on its low setting rather than cycling repeatedly from high to off. Multispeed blowers and two-stage gas valves are required. The control system will be much more sophisticated, often using electronic thermostats and controls.

Not only are multistage gas furnaces more efficient than the single-stage types, but because of the steadier operation, there is less fluctuation in room temperature. The slower speed of the blower at low firing reduces drafts and is quieter. Due to these reasons, multistage gas furnaces have been replacing the single-stage types.

Variable-Speed Furnaces

Variable-speed gas furnaces will use a variable-speed ECM (electronically commutated motor)-driven blower in combination with a computer-controlled thermostat. The furnace control system will adjust automatically to maintain a constant temperature. They are the most efficient and quietest type of gas furnace. Variable-speed blowers use significantly less electricity than traditional single-stage furnace blowers. Although variable-speed furnaces will cost more initially, they will save the customer money over time.

Warm-Air Gas Furnaces Compared to Hydronic Gas Furnaces

Hydronic gas furnaces heat water that is circulated through the building rather than circulating forced warm air. This is very common for oil heat. Hydronic systems are explained in detail in Unit 80, Hydronic Heating Systems. Ductwork is not required for a hydronic system. This can be seen as an installation advantage for areas of the country where central cooling is not always necessary.

Hot water is circulated through baseboard heaters or through radiant-heat piping installed under the floor joists or

Figure 50-1 Low-voltage thermostat used for heating only.

in the slab. Radiant heat piping has become increasingly popular and in some designs will also include a solar hot-water loop. A hydronic gas furnace can also be used in combination with water-to-water heat pumps and geothermal systems.

In general, however, traditional hydronic systems are difficult to adapt for cooling because additional ductwork just for cooling would need to be installed. Therefore, many of the gas hydronic gas furnaces are heat only (Figure 50-1).

In comparison, warm-air gas furnaces will have an installed ductwork system that can be used for both cooling and heating. This is ideal for the many areas of the country that require both. Therefore, the control thermostat for warm-air gas furnaces often includes both heating and cooling modes (Figure 50-2).

50.3 THERMOSTAT OPERATION

Thermostats automatically measure and maintain a desired room temperature. The key components of a thermostat are the temperature sensor and the temperature switch. The most basic type of thermostat configuration will send an electrical signal to turn the heating equipment on or off. Electromechanical thermostats utilize a snap-action effect

Figure 50-2 Low-voltage thermostat used for both heating and cooling.

to open or close contacts. They are designed to sense the temperature change of the room by using a bimetallic element. Electronic thermostats utilize thermistors or other integrated circuit sensors to sense temperature changes.

The cut-in point is the room temperature at which the thermostat will turn the furnace on, and the cut-out point is when the furnace is turned off. The difference between the cut-in and the cut-out is called the differential. A large differential will lead to a greater temperature swing in the room. A low differential will cause the furnace to cycle on and off more frequently.

Even though the cut-in temperature turns the furnace on, it will take some time before the room begins to warm up. This is known as system lag. Likewise, there may be some residual heat from the furnace even after it has shut off on cut-out, and this is called system overshoot.

Temperature swing is the range between the highest and the lowest room temperature controlled by the thermostat. This is affected by the differential, the system lag, and the system overshoot. Thermostats should be installed in a proper location and adjusted correctly to provide for comfortable room conditions with minimal temperature swings.

50.4 MECHANICAL THERMOSTATS

Mechanical snap-action thermostats (Figure 50-3) have been widely used. The use of spiral-shaped, lightweight bimetallic elements increases the effective length and thus the sensitivity to temperature change. Sealed contacts eliminate the problem of dirt and dust. Although there are minor variations among different manufacturers, the contacts are always sealed in a glass tube.

A single-action mercury bulb design is shown in Figure 50-4. As the bimetallic strip expands and curves,

Figure 50-3 Snap action thermostat.

Figure 50-4 A single-action mercury-bulb thermometer on the left; a sealed tube with metal-to-metal contact on the right.

Figure 50-5 Sub-base portion provides a mounting base for the thermostat and for system controls.

the mercury fluid moves to the left, completing an electric circuit between the two electrodes, which carry only 24 V. The differential gap between OFF and ON is very small: 0.75°F to 1°F from the setpoint. On the right is a sealed tube that has a metal-to-metal contact. The magnet provides the force that closes the contacts.

The sub-base portion of the thermostat assembly (Figure 50-5) not only provides a mounting base for the thermostat but is also used to control the system operation through a series of electrical switches. The system

switch selects COOL, OFF, or HEAT. The blower operation is controlled by the fan switch, which is a simple two-position switch. When set on automatic, the fan will cycle on and off with the system whenever there is a call for heating or cooling. In the ON position, the fan will run continuously.

More complex thermostats contain two adjustments that allow different control points for heating and cooling to be set. These thermostats may have an automatic changeover from heating to cooling. Figure 50-6 represents a two-stage cooling schematic wiring diagram. Two-stage thermostats are common in heat pumps or commercial rooftop equipment, which use multiple compressors for cooling and two or more stages of heating. Note that seven electrical connections are required; however, RH and RC terminals are the same power source, so six wires are needed. With color-coded low-voltage wire, however, it is no problem to connect the thermostat to the mechanical equipment.

GREEN TIP

The mercury found in mercury bulb thermostats is a deadly toxin. Mercury bulb thermostats should not be thrown away. They should be recycled so that the mercury can be safely recovered.

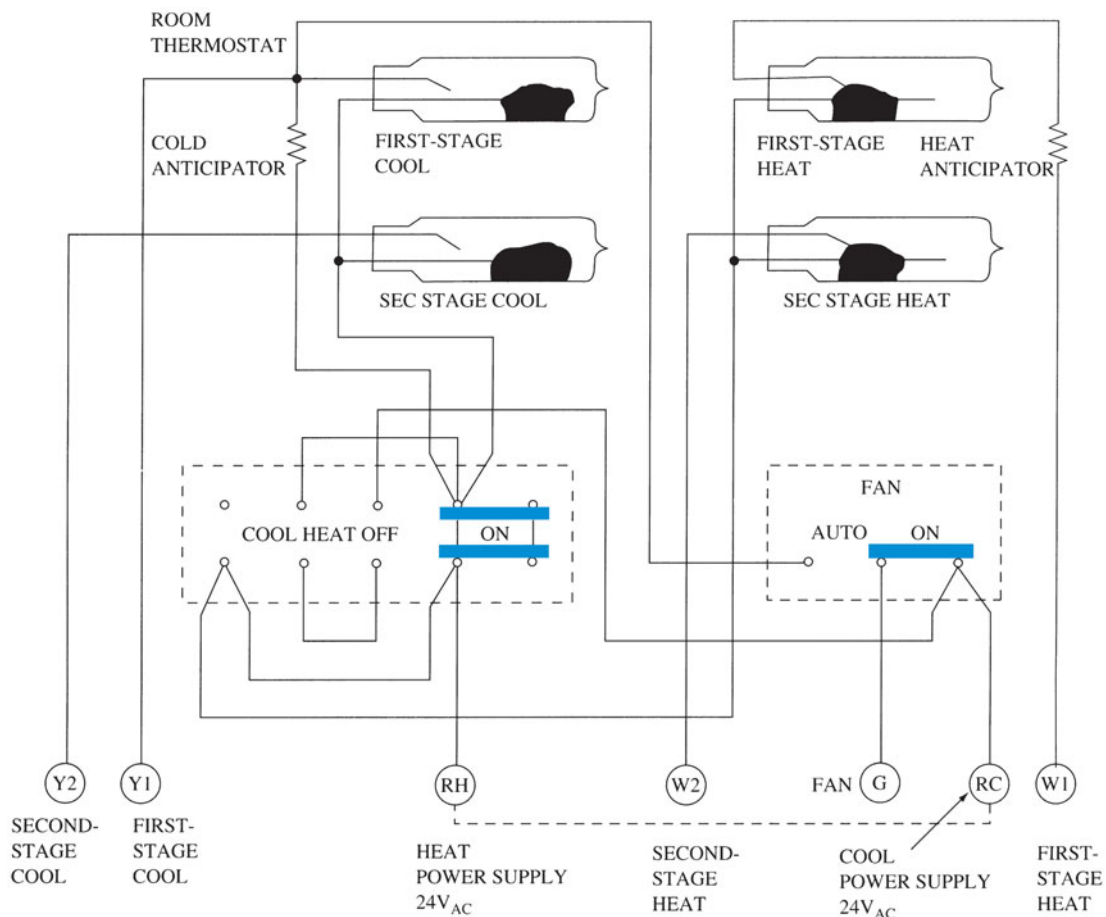

Figure 50-6 A two-stage heating and two-stage cooling schematic wiring diagram.

50.5 ELECTRONIC THERMOSTATS

Most thermostats today are electronic because they can maintain room temperature within less than a degree, do not use mercury, and can perform more functions than traditional mechanical thermostats. Electronic thermostats can be programmable or nonprogrammable. These thermostats often use thermistors or other integrated circuit sensors to sense temperature changes. Thermistor operation is based on the fact that the electrical resistance of a ceramic semiconductor changes as its temperature changes. Generally these thermostats have an LED or LCD display for enhanced readability. Electronic thermostats use relays or electronic switches to control system operation.

Programmable electronic thermostats can be programmed to set back the temperature at predetermined times and days (Figure 50-7). This allows for additional energy savings by automatically reducing the demand for heating or cooling—for example, at night or during the day when no one may be home. These can also provide additional information such as filter change reminders and system runtime data. Many of these thermostats provide for adjusting burner on-time and fan operation.

Single-Stage, Two-Stage, and Modulating Thermostats

Some furnaces can be configured with different thermostat arrangements. As an example, assume a furnace that modulates between 40 percent and 100 percent capacity is to be wired with a single-stage thermostat. The thermostat would need to be connected according to the manufacturer's wiring diagram, and the correct dual in-line package (DIP) switches would need to be turned off. With the switches off, the lack of the modulating signal will automatically be sensed as a single-stage thermostat. Instead of operating as a fully modulating furnace, this furnace will operate at the three different firing rates of 40 percent, 65 percent, and 100 percent. For the first 5 minutes of operation, the furnace will operate at 40 percent capacity. For the next 7 minutes, the furnace will operate at 65 percent furnace capacity. After 12 minutes, the furnace will operate at 100 percent capacity. If the call for heat ends, the furnace will shut off regardless of the firing rate at that time. When restarting, the furnace will once again start at 40 percent capacity.

Figure 50-7 Programmable electronic thermostat with LED display.

In comparison, a two-stage thermostat wired to the same furnace would provide different operating conditions. The first-stage heat would allow for continuous operation at 40 percent capacity. The second-stage heat would allow 65 percent capacity for the first 5 minutes and then 100 percent capacity continuously after that.

A modulating thermostat connected to this same furnace would allow for full modulation between 40 percent and 100 percent capacity. The firing rate is first determined by the thermostat and then sent to the furnace. This type of control would provide the best temperature control and furnace efficiency.

50.6 HEAT ANTICIPATION

Heat anticipators are used in mechanical low-voltage thermostats to reduce the temperature swing caused by the systems. Heating anticipators are small electrical resistors that generate a little heat inside the thermostat when the heat is on. This “false heat” on the bimetal tricks the thermostat into thinking the room has reached the set temperature. The furnace burner goes off when the thermostat thinks the room is warm enough, but the fan keeps running until the heat exchanger cools down. Without a heating anticipator, the room temperature would overshoot the set temperature. Temperature swing is the difference between the temperature when the furnace comes on and goes off.

Although heating anticipators result in closer room temperature control and less overshooting of heating, they can shorten the heating cycle time. If the heating anticipator is set too high, the furnace will short cycle.

Some heating anticipators are fixed, while others are wire-wound variable resistors wired in series with the load. They are rated in fractions of amperes. On the adjustable type, the installer will position the sliding arm to the proper load rating. A heating anticipator is shown in Figure 50-8. The initial setting should match the amp draw of the gas valve. But if on/off cycles are too long or too short, the system operation can be changed by adjusting the anticipator control lever to give a faster or slower response.

Electronic thermostats do not use false heat to anticipate when to cycle heating and cooling equipment. They can measure temperature changes of less than 1°F and are able to anticipate based on temperature changes and logic.

SERVICE TIP

Some customers are more sensitive to temperature change than others. These customers might have a complaint that the room gets too cold before the heat comes on. They might also complain that this occurs even when the temperature has been turned up slightly. What they are feeling is the temperature swing resulting from the heating anticipator being set too low. By raising the current setting on the heating anticipator, the heating cycle will shorten, and the temperature swing will decrease.

Figure 50-8 An adjustable heating anticipator.

TECH TIP

The longer a furnace runs during its heating cycle, the more efficiently it operates. Setting the heating anticipator so that a larger temperature swing occurs will result in energy savings. Conversely, a short-cycling heating system is less efficient to operate.

SERVICE TIP

Adding humidity to a residence during the heating season will allow your customer to feel more comfortable at a lower thermostat setting. A large part of a person's comfort is the rate at which perspiration evaporates from the skin. As the relative humidity goes up, that rate of evaporation decreases; thus people feel warmer even at a lower actual room temperature. A humidistat can provide that control, which will increase your customer's comfort and save heating costs.

50.7 FAN AND LIMIT SWITCHES

Fan Switch

The fan switch controls the starting and stopping of the blower motor. The fan does not start when the burner starts. Instead, the fan switch closes and starts the blower when the air temperature inside the furnace plenum chamber has warmed up to the FAN ON setting. The fan switch remains closed when the burner stops, keeping the blower in operation until the air temperature inside the furnace cools down to the FAN OFF setting. Modern furnaces cycle the fan based on time rather than temperature. A relay built into the control board energizes the fan 1-2 minutes after the burner lights. The relay turns the fan off 1-2 minutes after the burners shut off. The off delay is usually adjustable, Figure 50-9.

Figure 50-9 Blower off delay adjustment on furnace board.

Figure 50-10 Limit switch.

Limit Switch

The limit switch is a safety control that prevents the furnace from overheating Figure 50-10. As long as the plenum chamber temperature is below the setting of the limit switch, the switch remains closed. If the plenum chamber temperature rises to the switch setting, it opens to de-energize the heating control circuit and close the gas valve. Most limits today are connected to the furnace control board. In older furnaces the limit was either wired directly in the 24 volt circuit to the gas valve or in the line voltage circuit to the transformer primary.

Figure 50-11 Auxiliary limit switch.

Auxiliary Limit Switch

Downflow, horizontal, and multi-poise furnaces also have auxiliary limit switches located in the fan compartment because the blower compartment can become overheated by natural convection, Figure 50-11.

Combination Fan and Limit Switch

The combination fan and limit switch (Figure 50-12) is actually two switches in one. As a safety limit, some have fixed limit temperature settings; others are adjustable (approximately 180–200°F is the usual range). This allows a 50 to 60°F rise above normal operation before it opens. The fan control switch is also a temperature-sensing device that is set to turn on the fan after the furnace has warmed up at least 15 to 20°F above room conditions, so that cold drafts are not experienced. It also stops the blower after the burner cuts off, so again there are no uncomfortable drafts. It is important to note that some systems employ constant fan operation and thus override this switch.

Other models may use spiral, flat bimetallic, or even liquid-filled elements. Some forms of duct-mounted limit controls use a rod and tube or a liquid-filled bulb to sense the air conditions.

(a)

(b)

(c)

Figure 50-12 Combination fan and limit switch acts as a safety limit and temperature-sensing device.

Figure 50-13 Draft pressure switch.

Air-Pressure Switch

Furnaces that have a draft inducer may have an air-pressure switch that verifies air flow by monitoring the pressure differential between the draft inducer and the atmosphere Figure 50-13. Insufficient negative pressure indicates a lack of air flow and the ignition control module will shut off the gas supply. The draft switch is the first safety in the ignition sequence of most furnaces. The board checks to see that the draft switch is open before starting the draft inducer. After starting the draft inducer, the board checks to see that the draft switch is closed. If the draft switch does not close, the ignition process will go no further. Two-speed draft inducers require a dual air-pressure switch for both high- and low-speed air pressures Figure 50-14.

Flame Rollout Switch

Flame rollout can be caused by low air flow for a given burner firing rate or blockage in the vent system or heat exchanger. Flame rollout switches are located around the furnace cabinet near the burners, Figure 50-15 If flame rollout occurs and the temperature at the switch rises, the rollout switch breaks the circuit to the control module and the control module shuts off the gas valve. Normally the flame rollout switch must be reset manually before the furnace will restart.

Figure 50-14 Dual draft pressure switches for two stage furnace.

Figure 50-15 Roll-out switch mounted above burners.

50.8 IGNITION SYSTEMS

Standing Pilots

Older furnaces use standing pilot lights for ignition, but standing pilot lights are no longer used in modern gas

furnaces. A standing pilot is a small burner that is lit continuously. If the pilot flame goes out, the LP gas, which is heavier than air, could collect over a prolonged period to be a hazard. There are three types of flame-proving devices that will shut off the gas flow if the pilot flame goes out: thermocouples (thermopiles), bimetallic safety devices, and liquid-filled remote bulbs. As long as the pilot flame heats the flame-proving device, the gas safety valve remains open and the gas will flow when called for. If the pilot flame goes out and the flame-proving device cools, the gas safety valve will close. In most cases, the pilot will need to be manually reset.

Intermittent Pilot Ignition

An electronic intermittent pilot-ignition system is shown in Figure 50-16. Pilot gas is fed to the assembly and burner orifice. The spark electrode is positioned to ignite the gas on a signal from the room thermostat. With the pilot ignited and burning, a sensing probe establishes a small DC current of 2 to 50 microamps by using flame rectification. The control board energizes the main gas valve and de-energizes the

Figure 50-16 Gas furnaces that do not have a standing pilot are often referred to as being “pilotless.”

spark-ignition circuit. As long as the sensing probe recognizes the pilot flame, the gas valve will be energized and the spark-ignition system will remain de-energized.

SAFETY TIP

Approximately 10,000 V are generated in the spark-ignition circuit. Although the spark has very low amperage and is not considered a major safety hazard, it can cause a great deal of discomfort if it is energized while you are working in the area of the spark igniter or spark-igniter wire.

Direct Spark Ignition

The direct spark-ignition system (Figure 50-17) uses an electrical flame sensor rod mounted so that it has direct contact with the main burner flame. Because the gas flame will carry electrical energy by means of electrically charging the carbon atoms in the gas before combustion takes place, a current flow can be passed from the burner to a positively charged flame rod. When current is allowed to flow in only one direction, that current is said to be rectified. The flame rectifies the AC current so that it flows out of the flame as pulsed DC. This current flow controls a circuit in the solid-state control module and keeps the gas

Figure 50-17 Spark-ignition pilot assembly.

Figure 50-18 Pilot and gas valve controller.

valve energized (Figure 50-18). Flame rectification provides several unique features for a flame sensor. For example, if the flame rod has shorted against the furnace, it will pass the AC current through the furnace and the controller will not open the gas valve because pulsed DC is not present. Also, if the flame does not light, no current will flow, and again the controller will not open the gas valve. If the flame goes out, the controller will shut off the gas valve once the pulsed DC signal is lost.

Upon a call from the room thermostat, both the main gas valve and the spark igniter are activated. Allowing a predetermined time for main flame ignition, the ignition control module will shut down the lockout circuit and maintain burner operation if main flame ignition occurs in that period. The period may be from 4 to 21 seconds, depending on the model of control module used. Generally, a higher input to the gas unit results in a shorter proving time.

If the main burner flame is not established in the set time, the control module automatically locks out. To reset the circuit, electrical power to the system must be cut off and then back on to start another cycle. Manual reset of such a system is used for maximum safety to the equipment and building.

Because this system uses the main burner assembly as the ground terminal of the spark system, it is absolutely necessary that the gas burning unit be thoroughly grounded to the electrical supply ground. It is wise and usually necessary to run a ground (green) wire from the power-distribution panel to the unit to provide this positive ground. Because the white or neutral wire is a 120/240 V supply system, it is a current-carrying wire. It is not suitable for use as a unit ground.

Hot-Surface Ignition

A hot-surface ignition unit (Figure 50-19) is used for igniting the gas burners on many of the latest furnaces. This unit is made of silicon carbide, a material that has a very high resistance to current flow and when energized reaches the ignition temperature of gas. It is very tough and will not burn up, something like a glow coil. Even though it will last a long time, it is also brittle and will break easily with rough treatment. Make sure you do not touch the

(a)

(b)

(c)

Figure 50-19 (a) Hot surface gas fuel igniter; (b) hot surface gas fuel igniter located in furnace; (c) hot surface gas fuel igniter glows red before gas valve opens.

silicon carbide with your bare hand because it eventually will burn out where you touch it. The control system allows this material to reach the ignition temperature before the gas valve opens.

These units are powered by 120 V and draw a considerable amount of current when energized; however, they are used only a few minutes per day and therefore do not materially increase the electric bill. If the burner fails to light or the flame sensor fails to detect a flame after the gas is turned on for a few seconds, a safety lockout will occur to stop the flow of gas.

Figure 50-20 Combination gas valve.

50.9 COMBINATION GAS VALVES

At one time, supplying fuel gas to a heating unit was done by a combination of controls consisting of a gas pressure regulator, a solenoid valve, and a pilot safety valve. These controls were combined into a single valve assembly (Figure 50-20) to meet the standards for proper ignition, input control, and quiet cutoff of gas unit operation.

Combination gas valves have the following functions:

- Manual control for ignition and normal operation
- Pilot supply, adjustment, and safety shutoff
- Pressure regulation of burner gas feed
- On/off main gas valve controlled by the room thermostat

CAUTION

Unless you have received specific manufacturer's training on servicing gas valves, do not try to repair one that is not working. It is not safe for technicians to disassemble and reassemble gas valves and gas regulators. If it is determined that the problem is in the gas valve, it should be replaced and not repaired.

50.10 MAIN GAS VALVES

Main gas valves are used to control the flow of gas to the burner. The valve breaks down into four main parts: the valve body, seat, disk, and stem. Anytime the disk is lifted off the valve seat, gas will flow through the valve. Gas valves can be classified as either direct acting or pilot operated.

The solenoid, bimetal, and heat motor valves are all direct acting because the mechanism that is energized electrically to open the valve is also the device that mechanically opens the valve. Diaphragm valves are pilot acting; the diaphragm is what actually opens and closes the valve, but it is opened and closed by pressure difference. A small valve called an operator is energized electrically to control the pressure that opens and closes the diaphragm valve.

Direct-Acting Valves

The solenoid valve is the most familiar type of direct-acting valve. Solenoids may be normally closed or normally open, but most are normally closed. When power is applied to the coil, the magnetism created pulls the stem up, lifting the valve disk off of its seat. When power is turned off to the coil, the weight of the stem and/or spring pressure forces the stems back down, reseating the disk. Solenoids open and close quickly. This presents problems for some types of burners that work better if the gas pressure rises gradually, rather than instantly. To help solve this problem and reduce noise, solenoids have been made with springs and fluid to slow down the stem. Rubber and plastic seats and/or disks also help reduce noise and provide a more positive seal.

Another type of direct-acting valve is called bimetal. Bimetal valves are a slow opening by nature. They use a heater wrapped around a bimetal strip to open and close the valve. Voltage to the heater warms the bimetal, which causes it to warp, moving a soft disk or plug and opening the valve. Bimetal valves also close slowly since the bimetal must cool off before closing the valve.

Heat motor valves also use heat from an electrical heater to open the valve, but they use an expansible rod instead of a bimetal. An expansible rod is a rod inside a sealed cylinder that is filled with fluid. Heating the cylinder causes the fluid to expand and push the rod out. A disk is connected to the end of the rod and rests on the underside of the valve seat. Unlike the other direct-acting valves discussed, heat motor valves push the disk down to open the valve and spring pressure pushes the disk up to close the valve.

Diaphragm Valves

Most furnaces today use pilot-acting diaphragm valves. Operators control small pilot valves that control pressure to the underside of a diaphragm, causing the diaphragm to open or close. Operators can be a small solenoid, bimetal, or heat motor. The pilot valve controls a bleed port, which controls the pressure difference across the diaphragm to open and close the diaphragm. Underneath the diaphragm, the incoming gas pressure pushes up, tending to open the valve. Above the diaphragm is a bleed chamber. When it is open to the incoming pressure, the gas pressure also tends to push down, closing the valve. In other words, the same gas pressure is exerted on both sides of the diaphragm. The weight of the diaphragm and a slight spring pressure ensure that the valve remains closed when there is no pressure difference across the diaphragm. When the bleed valve is activated, the pressure in the bleed chamber is opened to the outlet side of the valve. Since this is usually atmospheric pressure at the beginning, it is lower than the incoming gas

pressure, which is pushing up on the diaphragm. The diaphragm lifts due to the higher pressure beneath it and lets gas flow through the valve. Even after gas enters the manifold, the pressure after the gas valve will be slightly lower than the pressure entering the gas valve, and the diaphragm will remain open as long as the bleed chamber is open to the outlet of the gas valve. When the operator is de-energized, the bleed chamber is closed to the valve outlet and opened to the gas inlet. The chamber pressure climbs to the incoming gas pressure and forces the diaphragm back down, closing the valve. Figure 50-21 shows a typical combination gas valve with a diaphragm-operated main valve.

Redundant Gas Valves

On standing-pilot gas valves, gas must pass through two shutoffs to exit the valve: the millivolt pilot safety solenoid and the main gas control. Because standing pilots are rarely used today, this has eliminated the need for the millivolt pilot safety shutoff. Most furnaces now use intermittent pilot ignition or direct ignition controls. They will use two automatic shutoffs that are mechanically in series to provide the same level of safety. These valves are called redundant gas valves because they have two valves to shut off the gas flow. Figure 50-22 shows a typical redundant gas valve.

Redundant Valves for Intermittent Pilot Ignition Systems

These systems replace the millivolt solenoid with a 24 V solenoid in line to the pilot burner and the main burner.

Figure 50-22 Redundant gas valve.

There is still a diaphragm valve for the main burner. The gas to the main burner has to go through both the solenoid and the diaphragm valve, providing redundant safety. The first solenoid is energized along with a spark igniter to light the pilot burner. Flame rectification is most often used for pilot proving. After the pilot flame is proved, the spark igniter is de-energized and the main burner valve is energized to light the main burner. If the pilot is not proved, the main burner valve will not be energized. On some systems, the spark igniter will keep trying to light the pilot while others will “lock out” after several failed attempts at lighting. “Locking out”

Figure 50-21 Cutaway of a combination gas valve in open position.

simply means that the spark igniter and first solenoid are de-energized and remain de-energized until the call for heat is killed and reinitiated.

Redundant Valves for Direct Ignition Systems

These systems do not use pilot lights, so the only gas flow is to the main burner. The two operators on these valves are energized at the same time. The gas must pass through both valves, providing two methods of shutting down the gas flow.

Two-Stage Valves

Many furnaces today achieve increased efficiency using two-stage gas valves (Figure 50-23). These gas valves have two firing rates: the first stage maintains a lower manifold gas pressure, and the second stage provides a higher manifold pressure (Figure 50-24). The lower firing rate of the first stage allows the furnace to operate longer in mild weather. This increases system efficiency by reducing startup and shutdown losses. Two-stage gas valves can be designed to operate with standing pilots, intermittent pilots, direct-spark ignition, and hot-surface ignition systems.

These valves use two pressure regulators (low fire and high fire) and two solenoids to provide two distinct stages of pressure regulation. Unlike the operation of the single-stage diaphragm valve described previously, the bleed gas flows through a first stage (low fire) regulator first rather than directly to the outlet side of the valve. This maintains the outlet at a pressure controlled by the low-fire regulator. When the second-stage solenoid is energized, the pressure above the main diaphragm is reduced. This

Start-up 1.2" w.c. manifold pressure

High Fire 3.5" w.c. manifold pressure

Figure 50-24 Start-up and high-fire burner flames.

causes the main valve to open more. The resulting increased supply of gas forces the low-pressure regulator to close and now allows the gas pressure to be controlled by the high-fire regulator.

The first-stage pressure setting is determined as a percentage of the full output of the valve, and often the pressure regulator is factory set. On some valves, both the low-fire and high-fire regulators can be adjusted separately (Figure 50-25). The highest low-fire pressure regulator adjustment will always be less than the lowest high-fire pressure regulator adjustment. The first-stage low-fire solenoid must always be energized first before the second-stage high-fire solenoid can energize.

Modulating Gas Valves

This type of gas valve will be used along with an integrated furnace control system. A modulating gas valve is shown

Figure 50-23 Two-stage gas valve location in furnace.

Figure 50-25 Two-stage valve showing adjustment for high- and low-fire manifold pressure.

in series with a two-stage gas valve in Figure 50-26. Both the gas flow and air flow are matched to correctly provide the proper firing rate. The furnace will operate over a heating output range of from 40 to 100 percent. The controller will sense both the supply- and return-air temperatures to determine the temperature rise. Based upon this, along with the thermostat input, the modulating gas valve and variable-speed ECM blower will be proportionally adjusted to maintain the proper firing rate and air-discharge temperature. Some advanced systems can also take into account other variables, such as gas heating values and air density.

50.11 GAS FURNACE WIRING DESIGNATIONS

Different manufacturers will have variations in the physical wiring, but the function remains the same in all systems. With a firm understanding of the construction and use of schematic wiring diagrams and sequence of operation, the student should be able to wire and understand any manufacturer's product. The industry uses standardized electrical symbols that help the technician identify the common controls. Also, alphabetic legend designations are used to help

Figure 50-26 Modulating gas valve in series with two-stage gas valve.

Table 50-1 Maximum Length of Two-Wire Run Based on Length and Current Capacity*

Wire Size	Amperes												
	5	10	15	20	25	30	35	40	45	50	55	70	80
14	274	137	91										
12		218	145	109									
10			230	173	138	115							
8					220	182	156	138					
6								219	193	175	159		
4									309	278	253	199	
3										350	319	250	219

1												399	349
0												502	439
00													560

*To limit voltage drop to 3 percent at 240 V. For other voltages, use the following multipliers:

110 V	0.458	220 V	0.917
115 V	0.479	230 V	0.966
120 V	0.50	250 V	1.042
125 V	0.521		

For example, the maximum run for #10 wire carrying 30 amps at 120 V is $115 \times 0.5 = 57$ ft.

Note that if the required length of run is nearly equal to, or even somewhat more than, the maximum run shown for a given wire size, select the next larger wire. This will provide a margin of safety. The recommended limit on voltage drop is 3 percent. Something less than the maximum is preferable.

identify the devices they represent. For example, R is a general relay, while CR is a cooling relay, HR is a heating relay, and DR is a defrost relay. Legends may vary with the particular wiring diagram or the manufacturer's method of labeling.

SERVICE TIP

Manufacturers include wiring diagrams inside of the furnace cabinet. Diagrams are also available from the manufacturer and supply house for each piece of equipment. Be sure to study these diagrams carefully because manufacturers may make minor changes in the circuits within the furnace from year to year. Do not assume that the diagram that you are familiar with from previously working on a similar unit is exactly the same. Check it out carefully.

50.12 WIRE SIZE

Wire sizes and fusing for independent appliances will be determined by the manufacturers and specified on their wiring diagrams. Local codes should be examined to determine whether conduit is required in bringing the wire from the main circuit breaker to the furnace or air conditioner. Some codes even require conduit for parts of the circuit operating on 120 V. Specification sheets will give the minimum wire and fuse sizes that will meet the requirements of the

National Electric Code, and this wire size is based on 125 percent of the full load current rating.

The length of the wire run will also determine the wire size, and Table 50-1 shows the maximum length of two-wire runs for various wire sizes. This table is based on holding the voltage drop to 3 percent at 240 V. For other voltages, the multipliers at the bottom should be used. If the required run is nearly equal to or somewhat more than the maximum run shown by the calculation in the table, the next larger wire size should be used as a safety factor. It is always possible to use larger wire than called for on the specifications, but a smaller wire size should never be used, as this will cause nuisance trips, affect the efficiency of operation, and create a safety hazard. All replacement wire should be the same size and type as the original wire and should be rated at 90–105°C (194–221°F).

50.13 CONTROL SYSTEM TRANSFORMERS

The step-down or low-voltage transformer that comes inside the furnace (Figure 50-27) is used in heating and air-conditioning control systems. This transformer is used to reduce line voltage to operate the control components. Inside a simple step-down transformer are two unconnected coils of insulated wire wound around a common iron core, as shown in Figure 50-28. To go from a 120 V (primary) to a 24 V (secondary), there are five primary turns to one secondary turn. For a 240 V, primary the ratio would

Figure 50-27 AC voltage transformer for low-voltage controls.

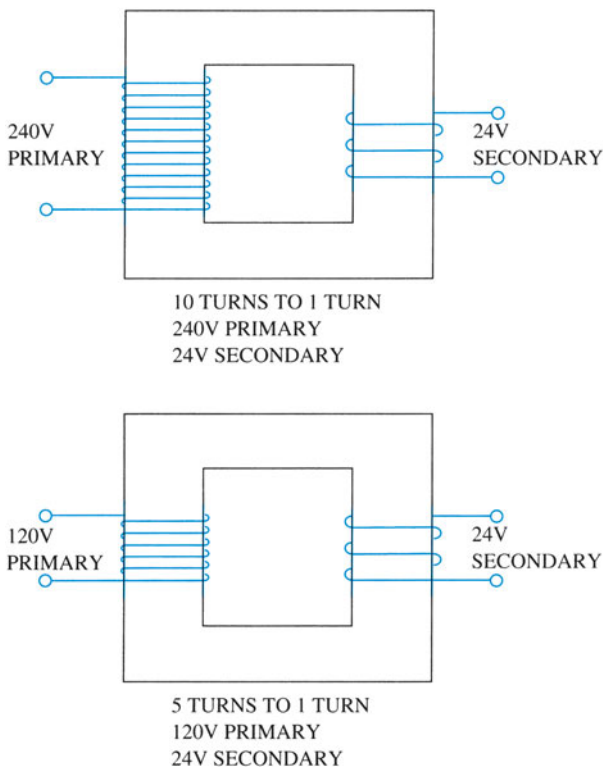

Figure 50-28 Construction of a step-down transformer.

be 10:1, and so on. This, the induction ratio, is a direct proportion.

Transformers used in the HVACR field are rated by their secondary power output. The most common size transformer found in residential gas furnaces is 40 VA. The term VA (volt-amp) is used to express the watts of secondary power output. To convert VA to amps of output, divide the VA rating by the secondary voltage rating.

EXAMPLE 50-1: SOLVING FOR TRANSFORMER SECONDARY CURRENT

A given transformer has a primary voltage of 120 V and a secondary voltage of 24 V. Assuming that the transformer is rated at 40 VA, what is the secondary current?

$$\text{Secondary (A)} = 40 \text{ VA} / 24 \text{ V} = 1.67 \text{ A}$$

SERVICE TIP

A standard 40 VA furnace control transformer has a very limited amperage capacity. If additional components such as humidifiers, duct boosters, and dampers are added to a system's control circuit, it may be necessary to increase the size of the transformer used.

Transformers are available in a variety of voltages and capacities. The capacity refers to the amount of electrical current expressed in volt-amperes. A transformer for a control circuit must have a capacity rating sufficient to handle the current (amperage) requirements of the loads connected to the secondary. Ratings of 40 VA are needed for air conditioning because electrical devices containing a coil and iron, such as solenoid valves and relays, have a power factor of approximately 50 percent. Thus, for secondary circuits with such controls, the capacity of a transformer must be equal to or greater than twice the total nameplate wattages of the connected loads.

The proper transformer rating for the electric control circuits will have been selected by the equipment manufacturer. If accessory equipment is added, however, the additional power draw must be considered. You may need to install a new larger VA transformer. This situation is common, for example, when cooling is added to an existing furnace and where the original transformer is too small. When replacing a defective transformer, make sure that the rating is equal to or greater than the original equipment.

50.14 SERVICING ELECTRONIC CONTROL BOARDS

Much of the equipment comes from the factory with electronic boards to control specific functions. When working on these units, it is necessary to get the service manual or technical sheet from the manufacturer's supply house. To help simplify the troubleshooting at the board level, identify four areas on the board: the input, output, board ground, and power supply Figure 50-29. The input is probably an on/off signal from a thermostat or variable signal from a thermostat that indicates a change has occurred. The output is the signal coming out of the board to activate a relay or controlled device. Most solid-state circuit boards rely on direct current to operate the electronic components, so they must be properly grounded. The power supply required could be high or low voltage, either 24 V AC or 5 V DC, or line voltage. If all four of these areas on the board are being provided as specified from the factory, there is a good chance the board has failed. It is not normally repaired in the field and

Figure 50-29 Input and output connections on furnace control board.

should be replaced. Prior to replacement, however, verify there are no electrical shorts or wiring problems that may have caused premature failure.

50.15 HEATING CIRCUIT

A simple schematic diagram for a typical gas-fired upflow air furnace is shown in Figure 50-30. The wire conductors are represented by lines and the other components by symbols and letter designations. Note the very important legend that identifies these. Typically, the schematic is the type of diagram used by service personnel to analyze the system.

Only five major electrical devices are in the diagram:

- The fan motor, which circulates the heated air
- The 24 V automatic gas solenoid valve, to control the flow of gas to the burner
- The combination blower and limit control, which controls fan operation and governs the flow of current to the low-voltage control circuit
- The step-down transformer, which provides 24 V current to operate the automatic gas valve
- The room thermostat, which directly controls opening and closing the automatic gas valve

To build this same schematic diagram, begin with the power supply. The wires for the power supply are usually run by the installing technician. They must carry line voltage (single-phase, 60 Hz, 120 V) to operate the blower motor and are represented by heavy broken lines to indicate field wiring (Figure 50-31). As a protection to the circuit, the power supply must be run through a fused disconnect switch. This is the main switch to the entire system.

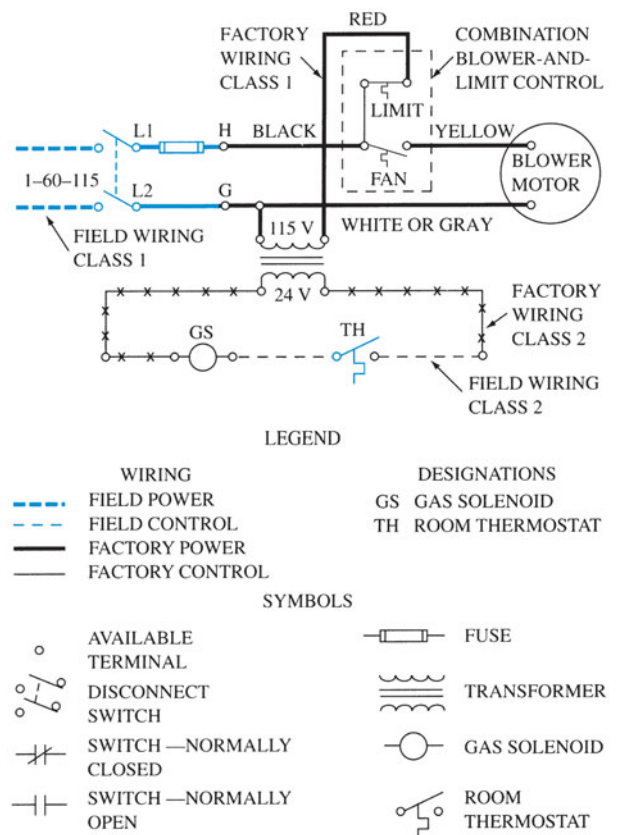

Figure 50-30 Heating circuit diagram for gas-fired upflow furnace.

Figure 50-31 Diagram for a fused disconnect.

Figure 50-32 Diagram showing the fused disconnect wired to the blower motor.

In a gas-fired heating system, the fan motor produces the heaviest load and is connected to the power supply (Figure 50-32). Since the fan motor is clearly identified on the diagram, it is not necessary to add it to the legend. Internal windings are not shown.

To test the system at this point, close the disconnect switch. The fan motor runs, since a simple circuit is completed from L1 through the windings of the blower motor and back to neutral. Open the disconnect switch and continue the diagramming.

Since there must be automatic control of both the fan motor and the automatic gas solenoid valve, connect the combination fan and limit control (Figure 50-33). This control, as previously described, consists of a sensing element, which measures the temperature of the heated air inside the furnace, and two adjustable switches: a fan switch and a limit switch.

As illustrated, the combination fan and limit control are partially connected. The fan switch is wired into L1 in series with the blower motor windings. If the disconnect switch is closed now, the fan motor will not run because the fan switch in the fan motor circuit is open and will remain open until the temperature in the furnace warms up to the switch setting.

Small electrical devices, such as relays and solenoid valves, do very little work and require little current for operation. A step-down transformer to reduce line voltage to 24 V is required and properly installed in the wiring diagram

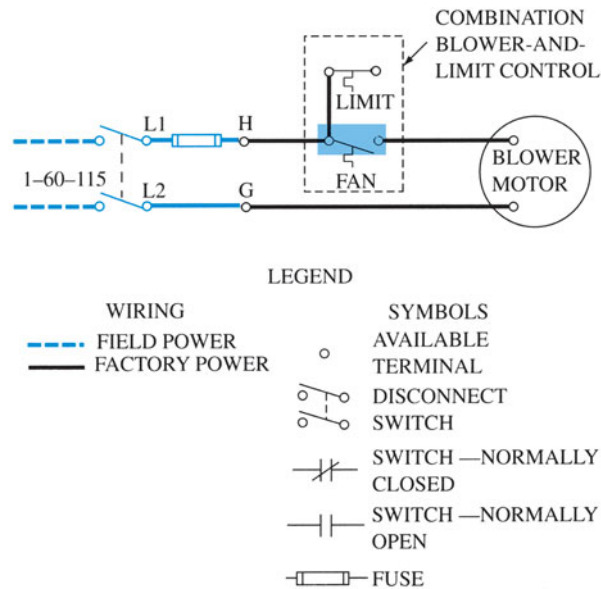

Figure 50-33 Wiring diagram showing the use of a fan limit control wired to a blower motor.

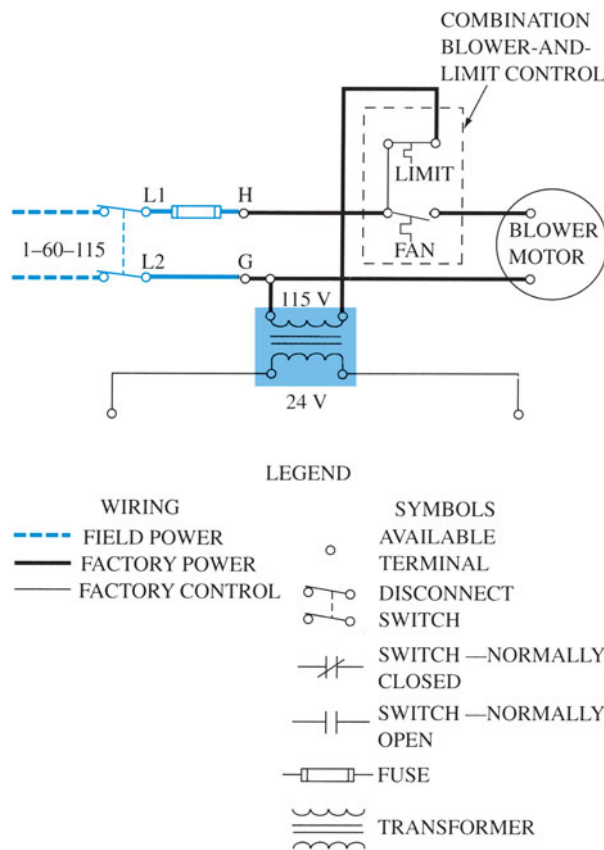

Figure 50-34 Schematic diagram showing the addition of a control circuit transformer.

(Figure 50-34). One side is connected to neutral and the other side is connected to L1 through the limit switch. This places the limit switch in control of the entire 24 V circuit.

If the disconnect switch is closed, the blower motor still cannot run since the fan switch must remain open until the air temperature warms up. The transformer and the

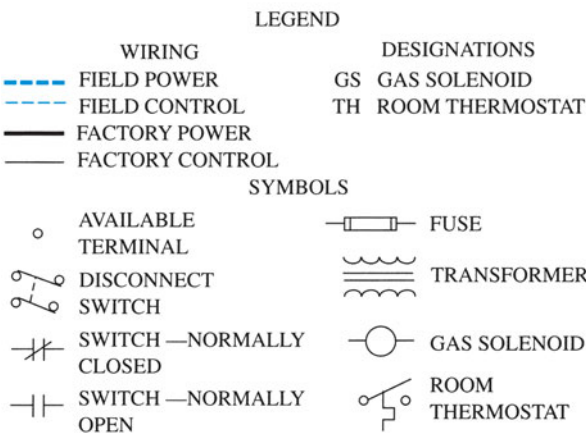

Figure 50-35 Schematic diagram of the low-voltage circuit showing the thermostat operation of the gas valve.

24 V power source, however, are energized immediately from L1 through the closed limit switch and back to L2. Although there is now a source of 24 V current, nothing can be accomplished until there is a circuit across the 24 V supply.

The automatic gas solenoid valve and room thermostat are wired in series across the 24 V circuit (Figure 50-35), since the opening and closing of the gas solenoid valve is controlled by the thermostat. The gas valve is factory wired as indicated on the diagram by a lightly shaded, unbroken line between terminals. Normally, the thermostat is located in a room away from the furnace and must be field wired, as indicated by the lightly shaded, broken lines used to represent control circuit field wiring.

The circuit is now completely wired. Close the disconnect and limit switches and open the thermostat. The transformer and low-voltage circuit are immediately energized from L1 through the closed limit switch back to neutral. With the thermostat open, the automatic gas valve remains closed. The fan motor cannot operate because the fan switch is open, and it will remain open until the air temperature in the furnace warms up to the FAN ON setting.

When the thermostat calls for heat, the automatic gas valve is energized (Figure 50-36) and the valve opens to

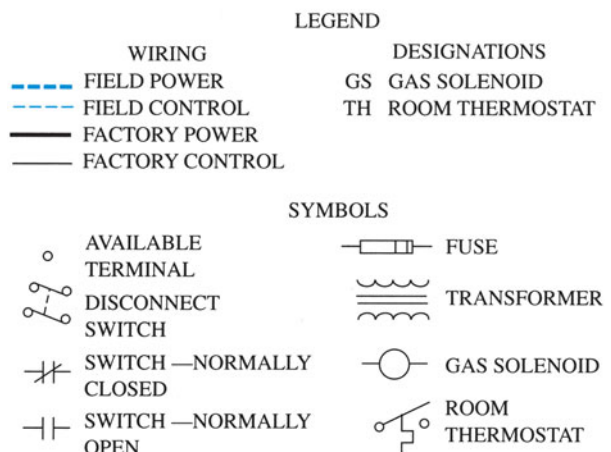

Figure 50-36 Schematic diagram showing the wiring of the limit control in series with the line-voltage side of the transformer.

admit gas to the burner. The fan switch would still be open so that the fan motor cannot run until the air temperature in the furnace plenum chamber warms up to the FAN ON setting.

Thermostat and gas valve circuits are reopened when the room-temperature setting is reached. Fan and blower contacts remain closed until the temperature of the heated air cools to the FAN OFF setting.

If at any time during furnace operation the plenum chamber overheats, the air temperature soon reaches the setting of the limit switch. This is an important safety switch, which opens at the overheating setting to de-energize the entire 24 V circuit. When this happens, the automatic gas valve closes, the burner is extinguished, and the thermostat is overridden. The fan switch remains closed and the blower continues to run as long as the heated air remains above the FAN OFF setting. The limit switch is manually reset by the service person after correcting the problem.

The operating sequence just completed proves that the wiring diagram is correct. The disconnect switch controls the entire electrical system; the blower motor operates independently of the burner, under the control of the fan switch. The automatic gas valve is cycled on and off by the room thermostat, under the control of the limit switch.

50.16 HOT SURFACE IGNITION OPERATION

Most gas furnaces manufactured today ignite the main burners directly using a hot surface igniter. Figure 50-37 shows a ladder diagram for a gas furnace with hot surface ignition. The draft fan relay (DFR), ignition relay (IR), cooling fan relay (CFR), and heating fan relay (HFR) are all part of the ignition control. The ignition control is shown in two places on the diagram because it is involved in both line voltage circuits (lines 1—6) and low-voltage circuits (lines 10—17). However, the ignition control is one physical device. The operating sequence used by most hot surface ignition systems is draft fan, igniter, gas valve, flame rectification, indoor blower.

With the system switch in the heat position, the heating thermostat closes when the room temperature drops. This initiates a call for heat, creating a path from the Red side of the transformer to the W terminal on the thermostat, through the limit and roll-out switches to the ignition control (line 14). The ignition control energizes the draft fan relay DFR coil (DRF line 14), closing the DFR contacts, which energize the draft fan motor (line 3). The draft fan motor operates for 60 seconds to perform a pre-purge. The pre-purge removes any lingering gas or combustion products from the burner and heat exchanger. Operation of the draft fan motor causes the draft pressure switch to close. After the pre-purge, the ignition control checks to see if the draft pressure switch is closed (line 13). The ignition process

does not continue until the draft pressure switch closes. After the ignition control sees that the draft pressure switch is closed, it energizes the ignition relay coil (line 16), closing its contacts and energizing the igniter (line 1). The igniter is energized for 60 seconds before the gas valve is energized. The gas valve is energized and the flame rectification circuit looks for the presence of flame (line 12). If flame is sensed, the gas valve remains energized and the igniter is de-energized. If flame is not sensed, both the gas valve and igniter are de-energized after five 5 seconds. The heating fan relay coil (line 17) is energized after a delay of two 2 to three 3 minutes. The normally open HFR contacts close to energize the heating fan speed and the normally closed HFR contacts open to prevent operation of the cooling fan speed (lines 5 and 6). Starting of the indoor fan motor is delayed to allow the furnace time to heat up. This prevents the fan from blowing cold air into the house.

UNIT 50—SUMMARY

A control system requires a source of power to operate, a load to utilize the power, and controllers to obtain the desired level of operation. Generally the operation of the system is under the control of a room thermostat, which controls a gas valve in the heating phase and the condensing unit's operation in the cooling phase. The blower in the gas furnace must operate intermittently in the heating phase, depending on the furnace supply-plenum temperature.

Heating control circuits are often designed to operate on low voltage because the wiring is simplified and safer. Furthermore, low-voltage thermostats provide closer temperature control than do line-voltage thermostats. A step-down transformer is used to reduce line voltage to operate control components. Heat anticipators are used in low-voltage thermostats to reduce the temperature swing caused by the systems.

Burner ignition methods are varied. A pilot is a small burner used to light the main burner when the gas valve opens. Standing pilots operate continuously while an electronic ignition system utilizes a spark electrode to ignite the gas pilot on a signal from the room thermostat. The direct-spark ignition system uses an electrical flame sensor rod rather than a pilot. A hot-surface ignition unit, rather than using a pilot, uses a silicon carbide material that when energized heats up to the gas ignition temperature.

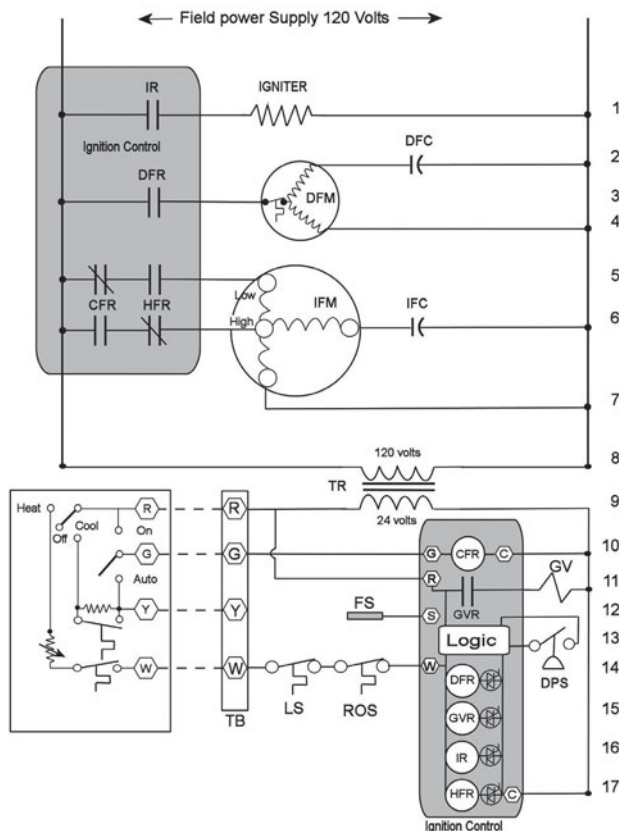

Figure 50-37 Schematic diagram for hot surface ignition furnace.

WORK ORDERS

Service Ticket 5001

Customer Complaint: Furnace Fan Keeps Short-Cycling

Equipment Type: 80,000 BTU Upflow Natural Gas Furnace

The technician analyzes the unit and discovers that the fan is short cycling with the burners off. The technician discovers the fan switch differential is set too narrow

(20 percent). The technician sets the fan to come on at 140°F and cycle off at 90°F, which is a 50°F differential. The technician runs the system through several cycles to ensure that it is operating properly. The system is now operating as designed.

Service Ticket 5002

Customer Complaint: Pilot Light Comes on Briefly, but the Burners Will Not Light

Equipment Type: 100,000 BTU Horizontal Gas Furnace

After talking to the customer, the technician decides to try running the system. After setting the thermostat to heat, the technician observes the spark igniter come on and light the pilot. After about 21 seconds, the pilot turns off without lighting the furnace. The technician determines that the flame sensor is bad. After disconnecting the main power, the technician replaces the flame sensor. The technician turns the power back on and sets the thermostat to heat. The spark igniter lights the pilot, and in just a few seconds the burner lights and the system operates normally.

Service Ticket 5003

Customer Complaint: The System Runs Fine on Cooling but Not on Heat

Equipment Type: 125,000 BTU Upflow NG Furnace

The technician checks the system and finds that it is not getting voltage between the common or C and W terminals. When the furnace is getting a heating signal, there will be no voltage read between R and W. It is probably less confusing to compare voltages to C common terminals in the furnace. The technician de-energizes the system and performs a continuity check back to the thermostat and finds that there was no continuity. The technician then checks for continuity between the R and W terminals on the thermostat with the thermostat set to call for heat. With no continuity between the thermostat terminals R and W, the technician replaces the thermostat. The technician returns power to the system and sets the new thermostat to call for heat. The system

operates normally in the heat settings. The technician cycles the thermostat a few times to ensure that the system is operating as designed.

UNIT 50—REVIEW QUESTIONS

1. List the four areas of an electronic control board that should be identified when troubleshooting.
2. Identify the reasons a low-voltage control circuit is more desirable than a line-voltage control circuit.
3. A given transformer has a primary voltage of 240 V and a secondary voltage of 24 V. Assuming the transformer is rated at 40 VA, what is the secondary current?
4. What is the standard transformer VA rating for most HVACR systems?
5. Why are heat anticipators used in low-voltage thermostats?
6. State the problem associated with setting a thermostat heat anticipator too high.
7. How is a humidistat similar to a low-voltage switch?
8. Explain the reason why adding humidity to a residence increases customer comfort.
9. On a fan/limit switch, what is the usual setting for the limit?
10. List the four functions of a furnace gas valve.
11. Describe how a main gas valve gets electrical power to open.
12. How many volts are generated in the spark-ignition circuit?
13. Why is it necessary that the gas-burning unit be grounded on a DSI system?
14. If a burner fails to light or the flame sensor fails to detect a flame, what happens to ensure the system is safe?
15. Identify the standardized electrical symbols for the following common controls: indoor fan relay, humidistat, manual reset, and crankcase heater.
16. If there is a 240 V circuit that will be carrying 30 A using #10 wire size, what is the maximum length of the two-wire run that would limit the voltage drop to 3 percent?
17. In question 16, what would be the answer if the wire size is #12, the voltage is 120 V, and the amperage is 15 A?
18. List the five major electrical devices in the heating circuit diagram in Figure 50-30.
19. Explain what a limit switch is, its function, and how it affects the control circuit.
20. State why the legend and the notes are important parts of an electrical diagram.

UNIT 51

Gas Furnace Installation

OBJECTIVES

After completing this unit, you will be able to:

1. explain the difference between natural gas and LP gas.
2. use a gas meter to check the gas input of a gas furnace.
3. use gas piping tables to size gas piping for a furnace.
4. use GAMA vent-sizing tables to determine the correct vent size for a furnace.
5. determine the correct size openings to provide combustion air for a furnace.
6. determine furnace temperature rise.
7. list acceptable ranges for flue gas CO percent, O₂ percent, excess air percent, and net stack temperature.
8. list safety precautions that should be practiced when starting a gas furnace.

51.1 INTRODUCTION

Modern gas furnaces are an efficient and safe way to provide whole house comfort. Increasingly, customers are choosing higher-efficiency models to control heating costs. However, the full energy savings will only be realized if the furnace is installed correctly.

Design innovations in modern furnaces have produced more efficient, safer systems than those of just a few years ago. Some of these innovations have changed the way furnaces are installed. Induced-draft furnaces, two-stage furnaces, condensing furnaces, and direct-vent furnaces all require special installation techniques. These innovative furnaces will not perform as designed if installed incorrectly. Proper installation is also crucial for safe operation. Despite the many safety features incorporated into today's furnaces, they cannot always guarantee safe operation if the installation is unsafe.

a pressure measurement). Burner designs will allow operation between 3 and 4 in wc manifold pressure. These pressures must not be exceeded. The actual operating pressure for any particular installation is determined by the gas heating value and the altitude. Table 51-1 shows a typical manifold pressure chart supplied with the installation instructions.

CAUTION

The diaphragm in a gas regulator is easily damaged with excessive pressure. Before pressure testing a gas piping system, the gas line should be removed from the gas valve and capped. This should be done even though there is a gas-line shutoff so that the pipe joints from the shutoff to the gas valve can also be leak checked.

51.2 NATURAL GAS

To check, test, and adjust a gas-burning unit for the highest operating efficiency, the unit must have the proper gas input, the proper adjustment of the burners, the correct amount of combustion air, proper venting, and the correct amount of air for heat distribution.

To arrive at the correct gas input, two important factors must be known about the gas:

- Heat content in BTU/ft³
- Specific gravity

Natural gas is a mixture of methane and ethane. Various sources have different heat contents in the range of 950 to 1,150 BTU/ft³. The specific gravity also varies between 0.56 and 0.72. These characteristics relate to sizing the piping and determining the amount of gas to be supplied to each burner.

Heating units are constructed to use gas-pressure regulators set at an output of 3½ in wc (water column,

51.3 CHECKING THE GAS INPUT

The quantity of gas a customer uses is recorded by a gas meter (Figure 51-1). Gas meters use dials to indicate the gas quantity (Figure 51-2). The two smaller dials, one for ½ ft per revolution and the other for 2 ft per revolution, can be used to measure a furnace's gas consumption. To determine if the correct amount of gas is being fed to the heating unit, it is necessary to find the feed rate through the meter. For accuracy, all other appliances must be turned off. If the pilot lights of the other appliances, including water heaters, are turned off, be sure to relight them before leaving. Usually, the requirements of pilot lights are so small that they are ignored.

Gas flow through the meter is determined by the time it takes the test dials to turn one revolution. To determine this time, the following formula can be used:

$$\text{Time (sec/ft}^3\text{)} = \frac{\text{seconds per hour}}{\text{ft}^3/\text{hr of gas}}$$

Table 51-1 Manifold Pressure Chart

Note: Orifice numbers shown in **bold** are factory installed.

To determine how long it would take for 142.8 ft³/hr of gas to flow, the formula would be set up as follows:

$$\text{sec/ft}^3 = \frac{60 \times 60}{142.8} = \frac{3,600}{142.8}$$

It will require 25.2 seconds for 1 ft³ of gas to go through the meter. Thus, the ½ ft³ dial would require 12.6 seconds

per revolution, and the 2 ft³ dial, 50.4 seconds per revolution. A stopwatch or a digital watch timing function is recommended.

The firing rate of the furnace will vary with altitude. Furnaces installed in higher altitudes have a lower firing rate because the lower air pressure delivers less oxygen to burn the gas. The gas flow is reduced to match the available

Figure 51-1 Residential gas meter.

(a)

(b)

Figure 51-2 Typical domestic gas meter dials in ft³.

oxygen. The gas flow is also adjusted to account for differences in gas heat capacity.

If adjustments in the gas flow need to be made to produce the required input, it can be done by adjusting the gas-pressure regulator, as long as the input pressure stays

Table 51-2 Schedule 40 Iron Gas Pipe Support

Pipe Size	Support Interval
1/2 in	6 ft
3/4 in	8 ft
1 in	8 ft
1 1/4 in	10 ft

within the 3–4 in wc range. If the adjustment cannot be made within this range, the gas orifice size for the burners needs to be changed. The manufacturer’s installation data supply information for selecting the orifice size and adjusting the manifold pressure to achieve the correct capacity (see Table 51-1).

51.4 GAS PIPING

Fuel gas piping is specified in national codes such as the National Fuel Gas Code or the International Residential Code, Section VI, Fuel Gas. Natural gas piping is typically schedule 40 iron pipe or corrugated stainless steel (CSST) designed specifically for fuel gas piping. The iron pipe is joined with threaded fittings using thread sealing compound that is rated for use with gas. CSST is joined using special fittings designed specifically for CSST. All gas piping should be supported at regular intervals. Typical support intervals are listed in Table 51-2. Pipe should be sloped ¼ in per 15 ft toward a drip leg. The gas piping at the furnace should include a shutoff valve, a drip leg, and a union (Figure 51-3). A furnace connected with CSST or a flexible gas connector does not need a union.

Before the gas is turned on, the gas piping should be pressure tested to at least 1.5 times the maximum working pressure or 3 psig, whichever is higher. Air, nitrogen, or carbon dioxide can all be used for pressure testing. Oxygen should never be used! To pressure test the gas line: close the manual shutoff valve to the unit, connect the pressure gauge to the gas piping, pressurize the piping, and then close the pressure source. The gas piping must hold the test pressure for at least 10 minutes. In many areas, the local inspector must see both the initial pressurization and the final pressure. After the inspector has signed it off, the air or nitrogen in the line is released outside. Leaving the pressure in the line can damage the gas controls in the furnace. It is important to use quality shutoff valves that will hold back the test pressure. In some areas, the line is not connected to the furnace until after this initial pressure test to avoid accidentally damaging the gas controls in the unit.

51.5 SIZING GAS LINES

Factors used to determine gas-piping size are as follows:

- 1. Gas line pressure
- 2. Specific gravity of the gas

Figure 51-3 The gas line to a furnace should have a manual shutoff valve, a drip leg, and a union.

3. Allowable pressure loss from the gas source to the unit
4. Maximum gas consumption
5. Piping length plus the equivalent length of all fittings and valves

Line Pressure

Gas lines can be operated at different pressures. Higher-pressure lines can carry more gas through smaller lines. Gas piping tables are built for a specific delivery pressure. Most residential systems operate at less than 2 psi, often as low as 6 in wc (1/4 psi). Commercial systems often operate at higher pressures, from 1 to 10 psi.

Specific Gravity

The pipe sizing tables are for a particular specific gravity gas. The specific gravity of natural gas is 0.6; the specific gravity of propane is 1.5.

Maximum Allowable Pressure Drop

The maximum allowable pressure drop is the difference in the gas pressure at the source and the appliance. Generally, residential gas piping is sized for a maximum pressure loss of between 0.35 in wc and 0.5 in wc.

Maximum Consumption

The maximum consumption of the unit is the most cubic feet per hour that the connected appliance will use. This is easily found by dividing the firing rate in BTUs per hour for the appliance by the BTU content of the gas. Natural gas has a heat content of approximately 1,000 BTUs per cubic foot. Propane's heat content is approximately 2,500 BTUs per cubic foot. These figures are close enough for most calculations, but the heat content does vary from one location to another. To make accurate calculations, contact the local gas distributor for exact heat content figures.

Piping Length

The piping length is the actual length in feet between the gas source and the gas appliance plus the equivalent length in feet of all fittings, valves, or obstructions. Most gas pipe sizing tables include allowance for a "normal" amount of fittings, eliminating the need to calculate equivalent length separately. For our purposes, we'll assume that all systems in this section are "normal" systems.

Using Piping Tables

To use the pipe sizing Table 51-3:

1. Determine the greatest length of piping from the source to the appliance.
2. Find a row with a length equal to or greater than that length.
3. This row is used for ALL appliances and ALL sections of pipe.
4. Use this row to find a cubic foot capacity equal to or greater than the capacity needed for each section of gas pipe.

Table 51-3 Capacity in Cubic Feet of Gas for 0.6 SG with 0.5" wc Pressure Drop

Nominal Pipe Size Rigid Schedule 40 Iron Pipe

150	40	83	144	322	482

Figure 51-4 Gas piping example.

51.6 PIPE SIZING EXAMPLE

Figure 51-4 shows our example: a house with two furnaces and one water heater operating on natural gas with a heat content of 900 BTUs/ft³. The system is piped with schedule 40 iron pipe. The basement furnace firing rate is 100,000 BTUs/hr, the water heater firing rate is 50,000 BTUs/hr, and the upstairs furnace firing rate is 80,000 BTUs/hr. The gas pipe runs 30 ft from the meter to the basement furnace, 10 ft from the basement furnace to the water heater, and 50 ft from the basement to the upstairs furnace. The basement furnace is 30 ft from the meter, the water heater is 40 ft from the meter, and the upstairs furnace is 80 ft from the meter. Therefore, the farthest distance is 80 ft. The 80-ft row in Table 51-3 will be used to look up all the gas pipe sizes, even the shorter runs. The CFH consumption of the appliances is $100,000 / 900 = 111$ CFH, $50,000 / 900 = 56$ CFH, and $80,000 / 900 = 89$ CFH. The main line must carry the total CFH capacity of $111 \text{ CFH} + 56 \text{ CFH} + 89 \text{ CFH} = 256$ CFH. Looking across the 80-ft row, the first column that has a capacity equal to or greater than 256 is 1 1/4 in pipe at 452 CFH. The main line will be 1 1/4 in. The 3/4 in pipe size, can carry 117 CFH, which is more than enough for each of the furnaces. Each furnace will be piped with 3/4 in. The water heater can be piped with 1/2 in since 1/2-in pipe will carry 56 CFH, which is the exact consumption of the water heater.

51.5 LIQUID PETROLEUM (LP) GAS

Propane and butane are refined from crude oil. Although mixed, they are separable by condensing them at their respective boiling points. Propane produces 2,522 BTU/ft³, and butane yields 3,261 BTU/ft³.

The LP gas industry has established a set incoming line pressure for all LP gas-burning appliances of 11 in wc. Therefore, it is only necessary to determine that the LP supply system is large enough to maintain 11 in wc at the units when the total connected load is operating. The LP supplier will provide the tank installation, pressure-regulating devices, and piping to the furnace, but the service person should be familiar with the hookup procedure.

There are two basic systems, as illustrated in Figure 51-5. The single system on the right uses only one pressure regulator located at the tank. The two-stage system shown on the left is used where the number of appliances and volume of gas must be greater. In this case, there will be a pressure regulator located at the tank and one on the house (Figure 51-6). The line pressure at the outlet of the tank regulator on the two-stage system is 10–15 psig, whereas it is 11 in wc on the single-stage system. The main supply line will carry more cubic feet per hour at the higher pressure. Sometimes it is necessary to connect from a single-stage system to a two-stage system if the supply lines are undersized.

With single-stage systems, the pressure on the inlet of the regulator will be direct tank pressure, and this will vary with fuel and temperature.

To ensure that the gas will flow from the tank into the supply system to the heating unit, the tank pressure must at all times be higher than the line pressure required to supply the system. To maintain a pressure of 11 in wc at the heating unit, allowing for a pressure loss in the line of 1/2 in wc, the minimum tank pressure would be 2 psig. This means that the minimum outside temperature must be considered when selecting the mixture of LP fuel.

Table 51-4 shows the tank pressure that will occur at temperatures of –30°F to +110°F for mixtures of propane and butane. From this table it can be seen that butane is not usable below +40°F and even propane will not develop sufficient pressures below –30°F. In extremely cold climates, tank heaters are used to ensure adequate fuel supply.

Figure 51-5 LP gas supply systems.

Figure 51-6 (a) First pressure regulator located at the tank; (b) second pressure regulator located at the house.

TECH TIP

Some local and state governments require specific licenses to work on LP systems.

51.6 COMBUSTION GAS VENTING

Gas manufacturers now recognize four distinct categories of vented appliances. Only Category I appliances may be connected to a traditional venting system. Building codes usually just state that Categories II, III, and IV should be vented per the manufacturer's instructions. Category IV furnaces are vented with PVC or other noncorrosive materials, such as stainless steel. The required material for any furnace is identified in the installation instructions. Materials other than those listed in the manufacturer's instructions are not permitted. Categories II and III require special venting systems, and these are normally expensive. For this reason, most furnace manufacturers no longer offer any Category II and III appliances. The rest of this section deals only with Category I and Category IV appliances.

Category I Appliance Venting

The development of 80 percent furnaces using draft-inducer fans created problems with the old vent tables that had been used for years. Vent sizes for fan-assisted appliances are smaller because of the fan assist and because vent gases with these furnaces are cooler, so condensation is more of a concern. This is why the vent tables now have separate listings for natural-draft appliances and fan-assisted appliances. The fan-assisted tables list two columns, a minimum rating and a maximum rating. If a vent that is too big is used with a fan-assisted furnace, condensation will occur in the vent.

To understand the GAMA Category I venting tables, you must first understand the terminology used in the tables, which is listed below.

Vent Table Terminology

- **Fan-assisted combustion systems** Fan-assisted combustion systems are appliances equipped with an integral mechanical means to either draw or force products of combustion through the combustion chamber and/or heat exchanger.

Table 51-4 LP Gas Tank Pressures (psig)

[illegible]

- **Fan min** Fan min refers to the minimum appliance input rating of a Category I appliance with a fan-assisted combustion system that could be attached to the vent.
- **Fan max** Fan max refers to the maximum appliance input rating of a Category I appliance with a fan-assisted combustion system that could be attached to the vent.
- **Nat max** Nat max refers to the maximum appliance input rating of a Category I appliance equipped with a draft hood that could be attached to the vent. There are no minimum appliance input ratings for draft hood equipped appliances.
- **Fan+fan** Fan+fan refers to the maximum combined input rating of two or more fan-assisted appliances attached to the common vent.
- **Fan+nat** Fan+nat refers to the maximum combined input rating of one or more fan-assisted appliance and one or more draft hood–equipped appliances attached to the common vent.
- **Nat+nat** Nat+nat refers to the maximum combined input rating of two or more draft hood–equipped appliances attached to the common vent.
- **NR** NR means not recommended due to potential for condensate formation and/or pressurization of the venting system.
- **NA** NA means not applicable due to physical or geometric constraints.
- **Draft hood** A draft hood is a device built into an appliance, or made a part of the vent connector from an appliance, which is designed to
 - a. Provide for the ready escape of the flue gases from the appliance in the event of no draft, back-draft, or stoppage beyond the draft hood
 - b. Prevent a backdraft from entering the appliance
 - c. Neutralize the effect of stack action of the chimney or gas vent upon the operation of the appliance
- **Vent** The vent is a passageway used to convey flue gases from gas-utilization equipment, or their vent connectors, to the outside atmosphere.
- **Vent connector** The vent connector is the pipe or duct that connects a fuel-gas-burning appliance to a vent or chimney.
- **Flue collar** The flue collar is that portion of an appliance designed for the attachment of a draft hood, vent connector, or venting system.
- **Categorized vent diameter** The categorized vent diameter is the minimum vent diameter permissible for Category I appliances to maintain a negative vent static pressure when tested in accordance with nationally recognized standards.

Venting Tables

The most authoritative vent-sizing tables are published by GAMA, the Gas Appliance Manufacturers Association (GAMA merged with ARI in 2007/2008 to form AHRI). Because there are many vent materials used and many types of equipment connected to vents, there are a large number of tables. Figure 51-7 illustrates the dimensions used in the GAMA venting table. This text covers only tables for use with single appliances vented with type B double-

Figure 51-7 Illustration of terminology used in venting tables.

wall vents and vent connectors. Examples of type B venting are shown in Figure 51-8.

Vent Sizing for a Single Appliance

Table 51-5 shows a vent-sizing table for a single Category I gas-fired appliance using a type B vent and vent connector. First, determine the total height of the vent from the top of the draft diverter to the cap. Next, determine the lateral distance the vent will be traveling. The lateral distance should never be more than the vertical height of the vent. Find the vent height on the left. If the actual distance is in between sizes, round down because taller vents work better than shorter ones. That way you are selecting the worst-case scenario. Find the lateral length in the column immediately to the right of the height column. If the actual length is in between sizes, round up, because longer lateral lengths reduce the vent capacity.

For natural-draft systems, read across under the Nat columns until you find the first BTU input rating equal to or greater than the input rating of the appliance. Read up to find the vent size. In no case should you use a vent size smaller than the connection on the draft hood.

For fan-assisted appliances, read across under the Fan min columns until you find the first BTU input rating equal to or less than the input rating of the appliance. Next, check the Fan max column, which is located next to the Fan min column. The furnace BTU capacity must be equal to or less than the Fan max rating and equal to or greater than the Fan min rating.

Category IV Furnace Venting

Category IV furnaces are generally vented with PVC because they operate with a positive vent pressure and the vent gases tend to condense in the vent. PVC can easily withstand the low vent-gas temperatures of a Category IV

(a)

(b)

(c)

Figure 51-8 (a) Type B combined venting for two appliances; (b) type B vent passing through roof; (c) examples of vent pipe flashing and round-top arrangements.

furnace, and PVC is easily sealed to contain the positive vent pressure. Other material can also be used, such as stainless steel, if approved by the manufacturer. Many Category IV furnaces are also direct-vent furnaces; their combustion air is piped in through another PVC pipe.

TECH TIP

On many direct-vent Category IV furnaces the air intake enters near the top of the furnace and the vent exits near the middle of the furnace (Figure 51-9). This is because they are using counterflow heat exchange to increase their efficiency. It is easy to get these backward because the air intake is often located where the vent is on a regular furnace.

Care must be taken when running the combustion-air line and the vent so that the vent products do not blow right back in the combustion-air line. One way to accomplish this is to turn the vent up and the air intake down (Figure 51-10). The vent and air intake should also terminate at least 12 in above the normal season snow line. Always follow the manufacturer's instructions when terminating a vent system. Failure to do so can have disastrous results, and in most cases the system will not pass inspection.

Category IV furnaces condense water as part of their operation. Additional water forms in the vent and drains back to the furnace. Part of running the vent system to one of these furnaces is running the drain. If the furnace is installed where the drain will not operate by gravity flow, a condensate pump will be required. Make sure the condensate pump is rated for furnace duty; the condensate from condensing furnaces can eat up the materials on some condensate pumps.

51.7 COMBUSTION AIR

Gas furnaces cannot operate without an adequate supply of combustion and ventilation air. As the furnace operates, it draws air out of the room it is in. Air is needed from outside to keep the furnace operating. In many older installations, the assumption was that enough air would infiltrate through leaks in the house to supply the combustion-air needs. This is not a safe assumption, especially as home construction actively tries to eliminate leaks. It is now common to wrap the entire house in a house wrap to seal out air leaks. Air must be supplied from outside for safe operation of gas appliances.

This can be accomplished with two rectangular openings, one within 12 in of the ceiling and one 12 in from the floor. These openings should be open to the outside. Each opening should have a minimum free area of 1 in² per 4,000 BTU of the input rating of all gas appliances. Ventilated attics and ventilated crawlspaces count as outdoors. Figures 51-11 and 51-12 show two ways to provide adequate combustion air.

Sometimes ducting will be needed to reach the outside. If vertical ducting is used, the free area stays the same. However, if horizontal ducting is used, the free area must be based on 2,000 BTU/hr per in² of the total input rating

Figure 51-9 The air intake is near the top and the vent exits near the middle on this direct-vent high-efficiency furnace.

of all gas appliances. The minimum dimension of any duct used is 4 in. Figure 51-13 shows an installation using horizontal ducts for outside combustion air.

Note that these areas are free areas. If a 6 in \times 10 in grill is placed over a 6 in \times 10 in hole, the hole no longer has a free area of 60 in² because the grill free area is only about 40 in². The free area of the grill must be taken into account.

Direct-vent furnaces do not need a combustion air opening to the room because they draw their combustion air in through a PVC pipe. Their combustion process is

Figure 51-10 Category IV furnace venting.

Figure 51-11 Installation with all outdoor inlet and outlet air openings in the attic; Openings are 1 sq in per 4000 BTU.

sealed; they pipe air in and vent combustion products out. The concentric vent (Figure 51-14) allows both vent pipe and combustion-air pipe to pass through a single opening in the roof or sidewall.

Many burners have an adjustment for the primary air. Primary air is the air that is mixed with the fuel in the burner before combustion. The air adjustment should be set to produce a soft blue flame. Too much primary air will produce a hard blue flame that will waste fuel. Insufficient

Figure 51-12 Installation with inlet air opening in the crawlspace and outlet air opening in the attic. Openings are 1 sq in per 4000 BTU.

Figure 51-13 Installation with inlet and outlet air openings through horizontal ducts. Openings are 1 sq in per 2000 BTU.

primary air will produce a flame with yellow tips. Insufficient secondary air causes incomplete combustion, which wastes fuel and forms carbon monoxide (CO) and soot.

Most high-efficiency furnaces use an in-shot gas burner and an induced-draft fan. Normally the only adjustment that is made on these burners is the gas pressure. Typical settings are between 3.2 and 3.8 in wc for natural gas and 11 in wc for propane. These burners do not have a primary air adjustment. Regulation of the gas flow is by the gas pressure and the size of the orifice. The flame characteristic is clear blue.

After checking and setting the BTU/hr input and adjusting the primary air shutters, the vent draft condition should be checked.

51.8 AIR TEMPERATURE RISE TEST

The temperature rise of the air through the heating unit should be set as specified by the furnace manufacturer. Figure 51-15 shows the proper insertion of dial-type thermometers into the supply and return plenums of the heating unit. Use a drill to make a hole large enough to take the $\frac{1}{8}$ -in-diameter stem of the dial thermometer. Close the hole with a sheet-metal screw after the test is completed.

The supply-air thermometer should be located far enough away from the surface of the heat exchanger to prevent the effect of radiant heat on the thermometer from the heat exchanger. This is usually a minimum distance of 12 in. If the thermometer can be located in the main duct off the supply-air plenum, the radiant effect will be eliminated.

TECH TIP

It is not always possible to get an ideal temperature location on furnaces that are located in equipment closets. Often the furnace plenum is not accessible. For these installations, a temperature taken at the closest register to the furnace can be used.

After the unit has operated long enough for the supply-air thermometer to hold a steady reading (a stabilized reading), the return-air temperature should be subtracted from the supply-air temperature and the temperature rise recorded. If the temperature rise is below the specified temperature, the heating unit blower is moving too much air, and the speed should be reduced. If the temperature rise is above the specified temperature, the blower speed should be increased.

The procedure for this would depend on the type of drive used on the blower. Belt-driven blowers are adjusted by changing the size of the motor or driving pulley, direct-drive permanent split capacitor (PSC) blowers by changing

Figure 51-14 Concentric vent passing through the sidewall should exit at least 12 in above the normal season snow line.

Figure 51-15 Measuring the air temperature rise through a furnace: (a) at the furnace; (b) at the return-air and closest supply.

the electrical connections to the motor, and direct-drive electronically commutated motors (ECMs) by changing the jumper on the blower board.

Belt-driven blowers use a combination of adjustable motor pulley (the driving pulley), blower pulley (the driven pulley), and drive belt (Figure 51-16). The speed of the blower is adjusted by changing the spread of the flanges of the driving pulley. Opening the pulley by spreading the flanges allows the belt to ride lower in the pulley, thus reducing the effective diameter of the pulley. This in turn reduces the pulley diameter rotation between the two flanges and reduces the blower speed.

Closing the pulley spread increases the drive pulley diameter, resulting in an increase in blower speed. The pulley usually has two set-screw flats to allow adjustment of the pulley in half-turn increments. Use these flats! Do not drive the set screw into the pulley adjustment threads, as this ruins the chance for future pulley adjustments!

After the blower speed has been set, the belt tension and alignment should be checked (Figure 51-17). The alignment is adjusted by changing the position of the pulley on the shaft. In Figure 51-18, the driven pulley on the left has a set screw that holds the pulley in position. If the set screw is loosened, the pulley can be moved up or down the shaft until

Figure 51-16 Motor pulley, blower pulley, and drive belt.

Figure 51-17 Aligning pulleys and tightening belts.

Figure 51-18 The driven pulley on the left can be adjusted for alignment by loosening the set screw.

the proper alignment is obtained. The pulley alignment can be checked by using a straight edge. Once properly aligned, the set screw can be tightened to hold the pulley in place. The belt tension must also be adjusted. It should be tight enough to avoid slippage but not so tight to cause excessive wear. Approximately $\frac{3}{4}$ to 1 in of play should be allowed for each 12-in distance between the motor and blower shafts.

TECH TIP

After the pulley has been adjusted and tightened, close the blower door and check the motor amperage. If the motor amperage is at or near the rated load amperage for the motor, it may be necessary to slow the blower down slightly to ensure that the motor does not overheat.

On direct-drive blowers, the choice of blower speeds is limited to the number of speeds built into the blower motor. On some heating-only units, the blower has only one speed, and no choice of temperature rise is available. If air conditioning is added to the unit, a change in blower motor or blower assembly is required to accommodate the additional pressure loss through the coil.

If the heating unit is equipped with a multispeed blower motor, observe which fan speed lead is connected: high, medium, or low. For the initial startup, it is recommended

Figure 51-19 Fan settings on furnace control board.

that the fan be set for medium speed, subject to verification when the temperature rise is obtained.

Most furnaces built today use control boards that have fan connections marked Heat, Cool, Fan, and Park. The blower speed used for heating goes on the Heat terminal. The terminals marked Park are dummy terminals that just give the unused speed wires a place to sit safely while not in use. Figure 51-19 shows the fan settings on a typical furnace control board.

On furnaces using ECM blower motors, the change in speed is accomplished by moving a programming jumper. Many boards actually have an airflow written on the board for each available programming option. Figure 51-20 shows a typical ECM blower control with dual inline processor (DIP) switches to adjust blower settings.

No matter how it is accomplished, increasing the blower speed will increase the CFM of air through the unit and lower the temperature rise. Conversely, lowering the blower speed will decrease the CFM through the unit and increase the temperature rise.

When increasing the blower speed, which increases the load in the motor, the amperage draw of the motor will also increase. A clamp-type ammeter should be used to check the motor operating amperage. If the required CFM causes the motor to draw more than its amperage rating, a motor or blower assembly of larger capacity will have to be substituted.

Figure 51-20 ECM blower control jumper setting.

51.9 EFFICIENCY TESTING

With the heating unit input set, the burners properly adjusted, and the unit operating at as close to desirable temperature rise as possible, the unit can be tested for operating efficiency. The objective of efficiency testing is to obtain as high an efficiency rating of the heating unit as possible, taking into account the operating cost, the equipment operating life, and the comfort obtained in the conditioned area.

It is necessary to reach adjustments that achieve a balance between operating cost (efficiency) and comfort. Standards that are used for efficiency testing are as follows:

- **Input** The unit must be supplied with the correct amount of fuel at 90–100 percent of its rated capacity.
- **Burner primary air adjustment** Burner flames should be soft blue without yellow color or flame lift.
- **Air temperature rise** Adjust the fan to obtain the manufacturer's specified temperature rise.
- **Fan control settings** The fan control should be set according to the manufacturer's specifications.
- **O₂** The percentage O₂ in the flue gas is an indicator of the amount of excess combustion air and overall combustion efficiency. It may be measured with an O₂ analyzer (Figure 51-21).

No O₂ in the flue gas indicates incomplete combustion and possible production of carbon monoxide. Acceptable readings for safe operation range from 7 to 9 percent. Readings above 9 percent indicate too much combustion air, which is detrimental to efficiency.

- **CO₂** The percentage of CO₂ in the flue gas is also an indicator of overall combustion efficiency. Very often the flue gas is tested for CO₂ rather than O₂. If possible, it is recommended to test for both. The operation range for CO₂ is the same as for O₂, which is 7–9 percent.

TECH TIP

Checking a gas furnace's fuel consumption as compared to heat output is a way of determining the actual operating efficiency of a particular system. This performance check is much like a driver confirming the fuel economy (miles per gallon) that his car is getting.

A means of recording such information is necessary so that it will become a permanent part of the unit operating and service history. This efficiency check sheet should include the information shown below.

Input

1. Type of gas: Nat. _____ Mixed _____ Mfg. _____
Prop. _____ Bu. _____
2. Heat content (BTU/ft³) _____
3. Specific gravity of the gas: _____
4. Main burner orifice drill size: Found _____ Left _____
5. Manifold pressure (in wc): Found _____ Left _____

Combustion Efficiency

1. Percent efficiency _____

Gas-burning equipment of standard design should always be capable of 75–80 percent efficiency. Unless the unit is of a higher-efficiency design (when the manufacturer's instructions and settings must be followed), an efficiency above 80 percent could adversely affect the draft of the unit as well as cause condensation of moisture in the chimney or flue pipe and on the surfaces of the heat exchanger. If the efficiency results are less than this range, the test should be repeated, checking and setting the proper input.

51.10 COMBUSTION EFFICIENCY

There are a number of measurements that can be taken to determine the combustion efficiency of a gas furnace:

- Ambient temperature (temperature around the furnace)
- Stack temperature (vent temperature)
- Oxygen percent in the flue gas
- Carbon dioxide percent in the flue gas

The first two measurements are used to calculate the net stack temperature, which is found by subtracting the ambient temperature from the stack temperature. Take the temperature before the draft diverter when taking it on a natural-draft furnace. The oxygen and carbon dioxide readings are taken by drilling a small hole in the vent and taking a sample of the gas. This can be done with an aspirator connected to an hourglass shaped tester (Figure 51-22). The combustion efficiency is found using a slide rule provided with the combustion efficiency test kit.

All of these measurements can also be taken using an electronic combustion analyzer. The analyzer takes the sample, measures the oxygen percentage in the flue gas, measures the net stack temperature, and calculates the combustion efficiency. The analyzer can also calculate the CO₂ and excess air percentages. Figure 51-23 shows a typical electronic combustion efficiency analyzer.

Acceptable readings for atmospheric gas burners are the following:

Oxygen percent	7–9%
Carbon dioxide percent	7–9%
Excess air percent	50%
Net stack temperature	325°F–500°F

51.11 STARTUP SAFETY

Technicians should always be conscious of the unique hazards posed by combustible gases when working with gas furnaces. Gas appliances are safe when installed and operated according to the manufacturer's instructions, but technicians should not assume that everything is per the manufacturer's instructions. In fact, they should assume the opposite. It is reasonable to assume that a system that is not operating properly is either installed incorrectly or has a component that is not performing as designed. Either situation could

Figure 51-22 Carbon dioxide (CO₂) analyzer.

Figure 51-23 Electronic combustion analyzer.

create a hazard for the technician. There are a few precautions a technician can take that will reduce the chance of injury even if the furnace is potentially dangerous.

- Do not turn anything on until you have inspected the furnace! Check for the key safety items listed below. For example, turning on a system with a leak that has caused a buildup of gas could create an explosion.

- Check for the presence of gas in the area around the furnace. Use your nose or an electronic combustible gas sniffer to check for the presence of gas around the furnace. If gas is detected in the area of the furnace, the cause should be found and corrected before proceeding.
- Make sure there are no combustible items stored near the furnace. This is especially true of any volatile liquids that create vapors that can be ignited. These should not be in the same room!
- Check the vent. Make sure there is a properly connected vent and that the vent is in good shape. Vent gases spilling out into the area the technician is working in can overcome the technician.
- Check for combustion air. Do a quick visual check to determine where the combustion air will come from. A furnace operating without enough combustion and ventilation air will start producing carbon monoxide after a few minutes of operation.
- Do not position yourself directly in front of the furnace while it is lighting. If the problem with the system causes delayed ignition, a flashback or mini-explosion can occur. The flames normally will shoot straight out of the furnace; you do not want to be in their path.
- Once the furnace lights, check the vent to make sure it is working. This can be done by checking the draft pressure in the vent.

These safety precautions will safeguard the customer as well. There are a few additional items that may not present an immediate hazard to the technician but can present a hazard to the customer.

- Check the clearance to combustibles. Unit installation instructions will give specific clearances. A single-wall vent should have a clearance of at least 6 in; a double-wall vent should have a clearance of at least 1 in. Downflow furnaces installed on a wood floor generally require a noncombustible base to shield the combustible flooring under them.
- Make sure the door safety switch works. The door switch usually needs to be disabled to work on the furnace. Make sure to restore it to operating condition before leaving. The purpose of this switch is to prevent the furnace from operating with the door removed. Operation with the door removed would allow the combustion gases to be sucked out of the vent by the indoor blower, and they would begin circulating throughout the house.

51.12 OPERATIONAL CHECK

For Category I and II furnaces, place a draft gauge in the vent and check the draft with the burners operating. You should have a draft of at least -0.02 in wc. Watch the draft reading when the indoor blower comes on. A reduction in draft or an increase to a positive pressure indicates a leak in the heat exchanger. This is a serious safety issue that generally warrants replacing the furnace.

Check the manifold gas pressure after the burners light. The correct manifold gas pressure at sea level is indicated on the furnace nameplate. The manifold pressure is usually slightly less at higher altitudes. The manufacturer's installation instructions are the best source of information for de-rating gas appliances.

Look at the color of the flames: they should be blue. Yellow flames indicate incomplete combustion and the presence of carbon monoxide.

Yellow flames are the result of too much gas, too little air, or faulty burners. Older gas furnaces have adjustable primary air intakes. The primary air can be adjusted until the yellow disappears. However, opening the shutters too far can cause delayed ignition, especially on cold days. Too much primary air also causes the flames to lift away from the burner face. In-shot burners used in most modern furnaces do not have any primary air adjustment. Yellow flames from an in-shot burner indicate a lack of combustion air in the room or too much gas. Check the orifice size against the manufacturer's specifications or an orifice chart to make certain the furnace has the correct size gas orifices.

The combustion gases in the vent should be checked for carbon monoxide. Ideally, the carbon monoxide level should be 0 parts per million for complete combustion. Realistically, it is common for some low level of CO to be present in the combustion gases. Levels of CO in the vent gases exceeding 50 parts per million will warrant a closer look at the combustion process (Figure 51-24).

After the blower has been operating for a few minutes, check the temperature of the air entering and leaving the furnace. The difference is the temperature rise. Be sure to check the leaving air temperature in a location that is not directly in the line of sight of the heat exchanger. If the thermometer can "see" the heat exchanger, it may read higher due to the heat exchanger's radiant heat. If the temperature rise is too high, the airflow needs to be increased. If the temperature rise is too low, the airflow needs to be reduced.

Figure 51-24 Portable CO (carbon monoxide) analyzer.

51.13 PRACTICING PROFESSIONAL SERVICES

Service technicians should always remember that their job is not simply to push reset buttons and sell parts but to provide a service to the customer. Generally, the customer is paying more for the services being rendered than for any parts being used. They have a right to expect professionalism. Technicians should maintain an active interest in training and education and pursue professional NATE certification.

TECH TIP

Part of being a professional is practicing safe work habits. Keeping yourself and your customers safe is a professional responsibility all technicians should take very seriously.

UNIT 51—SUMMARY

Furnaces must be installed according to the manufacturer's instructions if they are to perform safely and efficiently. When installing a gas furnace, particular attention should be paid to clearances, combustion air, and venting. When performing the operational check, the manifold pressure should be set per the manufacturer's instructions and the primary air to the burners adjusted if necessary. The vent should be checked for proper operation, including a check of the drain for 90 percent annual fuel utilization efficiency (AFUE) furnaces. The furnace temperature rise should be checked and the airflow adjusted to keep the temperature rise within the manufacturer's specifications.

WORK ORDERS

Service Ticket 5101

Customer Complaint: Furnace Will Not Operate

Equipment Type: 90 Percent Direct-Vent Condensing Furnace Installed in Basement

A new 90 percent direct-vent furnace was installed in the fall and worked without any problems until recently. The technician observes that the induced-draft blower starts, but nothing else happens. The technician checks the pressure in the combustion air pipe and finds it in a vacuum of 0.5 in wc. The combustion air and vent pipe exit high on the basement wall, just above the grade level. Walking outside, the technician sees that the combustion air pipe is buried in snow. After digging the snow away from the air intake, the furnace operates. The technician re-pipes the combustion air and vent pipes to be well above the snow line.

Service Ticket 5102

Customer Complaint: Water All over the Floor

Equipment Type: 90 Percent Direct-Vent Condensing Furnace Installed in Basement

A customer has called about a furnace that was installed 6 months ago. When she got up this morning, there was water all over the floor, mostly by the furnace. The technician observes that the condensate pump can be heard running, but the water level in the sump is not going down. The technician checks the condensate water discharge line for kinks, but the line appears to be fine. The end of the line appears to be open as well. The technician lifts the pump out of the sump and opens it to find that the pump impeller has disintegrated. While inspecting the pump, the technician notices a sticker that reads, "Not for use with condensate from condensing furnaces." The technician explains that the pump was not designed for furnace use and recommends replacing the pump with one that is approved for furnace use.

Service Ticket 5103

Customer Complaint: CO Alarm Sounding

Equipment Type: Upflow 80 Percent Induced-Draft Furnace Installed in Hall Closet

A customer complains that since he moved in to his newly constructed house, the CO alarm in the hall periodically goes off. It seems to happen more often when there is a fire in the fireplace. The technician looks at the furnace closet and notices several boxes stacked up beside it from floor to ceiling, but no combustion air vents are visible. The technician finds the combustion air vents after moving the boxes. The technician asks the homeowner to start a big fire in the fireplace and then proceeds to check the furnace operation. The draft in the vent reads -0.03 in wc, and no CO is detected around the furnace. The technician explains that the boxes blocked the combustion air vents, creating a negative pressure in the furnace closet and resulting in the production of carbon monoxide. The technician advises the customer that the furnace closet should not be used for storage.

Service Ticket 5104

Customer Complaint: Supply Air Not Hot Enough

Equipment Type: 80 Percent Induced-Draft Furnace Installed in Crawlspace

A customer complains that the air coming out of the registers is not hot enough. The technician checks the manifold pressure and temperature rise. The manifold pressure is 3.5 in wc and the temperature rise is 20°F . The furnace data plate calls for a temperature rise of $25^{\circ}\text{--}50^{\circ}\text{F}$. The technician checks the fan taps on the control board and notes that the blower's highest speed is on the Heat position and the blower's lowest speed is

on Park. The low speed is moved to Heat and the high speed to Park. The technician rechecks the temperature rise and finds that it is 35°F.

Service Ticket 5105

Customer Complaint: Furnace Only Runs for 10 Minutes

Equipment Type: 80 Percent Multiposition Induced-Draft Furnace Installed in Crawlspace

A technician is called to check a furnace that was recently installed to replace an old horizontal furnace in a crawlspace. The homeowner explains that a friend of his did the change-out to save him money, but he is too busy at work to come by and take a look. The furnace will start and operate correctly for a few minutes, then the vent gas safety switch trips. The technician notices that the furnace was never reconfigured for horizontal installation and that it is connected to the old single-wall vent connector, which runs horizontally for 30 ft before entering a masonry chimney. The technician explains to the customer that the vent is not operating properly and that is causing the safety switch to trip. The technician recommends orienting the furnace for horizontal operation, replacing the single-wall vent with double wall, and lining the masonry chimney with a metal chimney liner so the furnace can vent properly.

UNIT 51—REVIEW QUESTIONS

- List the safety precautions that should be observed when starting a gas furnace.
- Explain the difference between natural gas and propane.
- What is the most common manifold pressure for natural gas furnaces?
- What is the most common manifold pressure for propane furnaces?
- A technician is clocking the gas usage of a gas furnace. It takes 30 seconds for the $\frac{1}{2}$ -ft dial to make one revolution. What is the rate of gas flow in cubic feet per hour?
- Use the gas flow rate calculated from question 5 to determine the input in BTU/hr if the heating capacity of the gas is 950 BTU/ft³.
- What is the correct vent size for a 50,000 BTU/hr input induced-draft furnace with a 15-ft lateral run and a 30-ft vent height?
- What is the smallest fan-assisted furnace that can be connected to an existing 6-in type B vent that is 30 ft high with a lateral run of 15 ft?
- What size should the combustion air openings be for a room with an 80,000 BTU/hr input furnace and a 35,000 BTU/hr water heater if the openings are opening directly into a ventilated attic and a ventilated crawlspace?
- What size should the openings be in question 9 if the air is traveling through horizontal ducts to the outside?
- Where do you measure the temperature when checking furnace temperature rise?
- What is the temperature rise of a furnace with a supply-air temperature of 130°F and a return-air temperature of 75°F?
- How can the temperature rise of a furnace be reduced if it is too high?
- What are the normal oxygen and carbon dioxide percentages in the flue gas in a properly operating gas furnace?
- How is net stack temperature determined?
- What is the lowest temperature at which butane can be used as a heating fuel?
- What is the difference between vent sizing for natural-draft appliances and fan-assisted appliances?
- Why are most furnaces manufactured today either Category I or Category IV furnaces?
- What is the difference between a vent connector and the vent?
- How is the correct manifold pressure for any particular installation determined?

UNIT 52

Troubleshooting Gas Furnaces

OBJECTIVES

After completing this unit, you will be able to:

1. list safety precautions to follow when working on gas furnaces.
2. list the general sequence of operation for an induced-draft furnace.
3. interpret an LED fault code on a furnace board.
4. diagnose a system problem using a troubleshooting flowchart.
5. use a wiring diagram to identify system problems.

52.1 INTRODUCTION

Any heating service organization is aware of the accumulation of service calls during the fall of the year. When homeowners first try to start their systems, the problems reveal themselves. The most serious of these is “no heat.” Whenever a no-heat call is received, it receives top priority. It means that for some reason the furnace will not run. The technician must solve the problem as quickly as possible.

Preliminary information is essential. What type of furnace is being used? What type of fuel is being supplied? Has the unit operated properly in the past, or is it a new installation? What has the customer done to get the unit started? Does any part of the unit run, or is it completely “dead”?

52.2 TROUBLESHOOTING GAS FURNACES

Gas furnace problems generally fall into two broad areas: electrical problems and combustion problems.

Troubleshooting the electrical problems is similar to isolating electrical problems with any appliance. If nothing is working, you start by checking power and control voltage to the unit. If the unit operates incorrectly, you determine what is not operating, determine if it has the correct operating voltage, consult the diagram, and check the circuits systematically to isolate the cause.

SAFETY TIP

Technicians should always be conscious of the unique hazards posed by combustible gases when troubleshooting gas furnaces. Even problems that are electrical or mechanical in nature can create explosion hazards. A safety control that fails to shut off a gas valve after a failed ignition attempt can allow a buildup of gas that can explode on the next ignition trial.

Combustion problems can be tricky, but understanding the effects of the three necessary components of combustion will help. Combustion requires three things: fuel,

Figure 52-1 Correct burner flame for gas heater with standing pilot and flame rod.

oxygen, and heat. If any one of these is not present, there will be no combustion. Further, if the gas and air are not mixed in the proper ratio, combustion will either not occur or will be incomplete. A visual inspection of the burner can often identify problems that should be followed up with a thorough combustion analysis. Figure 52-1 shows a correctly operating gas burner.

Too Little Gas at the Burners

The gas is normally delivered through an orifice at a pressure established by the manufacturer. Common manifold pressures are 3.5 in wc for natural gas and 11 in wc for propane. Low gas pressure can cause smaller than normal flames or delayed ignition. Figure 52-2 shows a gas burner operating with a low gas pressure. Check to see that the pressure at the inlet of the gas valve is at least the minimum supply pressure listed on the unit, usually 4.5 in wc for natural gas and 11 in wc for propane. Low gas supply pressure can be caused from undersized gas piping, restrictions in the gas line, or supplier problems. Next, check the manifold pressure leaving the gas valve; it should be close to the

Figure 52-2 Burner with too little gas.

manifold pressure rating listed on the unit. Try adjusting the outlet pressure if it is too low. If the inlet pressure is all right but the outlet pressure cannot be adjusted to the correct pressure, then the gas valve is defective.

Too Much Gas at the Burners

Too much gas will cause large, lazy, yellow flames that produce soot. Too much gas is usually caused by oversized orifices. Check the orifice number against the manufacturer's specifications. This can occur when changing a furnace from natural gas to propane because natural gas orifices are much larger than propane orifices for the same firing rate. A defective gas valve can also cause this. Check the manifold pressure and compare it to the manifold pressure listed on the unit. Try adjusting the outlet pressure if it is too high. If the inlet pressure is all right but the outlet pressure cannot be adjusted to the correct pressure, then the gas valve is defective. Figure 52-3 shows a gas burner operating with too much gas pressure.

Figure 52-3 Burner with too much gas.

Figure 52-4 Burner with too little primary air.

Too Much Primary Air

Too much primary air will cause delayed ignition and noisy flames that lift off the burner. This problem gets worse when the air is colder. The solution is to close off the primary air shutter until the flames have yellow tips, then gradually open the shutter until the yellow tips disappear.

Too Little Primary Air

If the primary air is closed completely, the flames will be lazy and yellow, similar to having too much gas. If the primary air is just not open enough, the flames will be blue at the bottom and yellow at the tips (Figure 52-4). The solution is to gradually open the shutter until the yellow tips disappear.

Improper Venting

If the vent does not work properly, the combustion products will build up in the vent and the flames will start to come out of the combustion chamber. Usually the furnace lights and burns correctly for a minute or two before this starts. The flames may also turn from blue to yellow. This can be caused by a blocked vent or by a severe lack of combustion air to the room. This condition is extremely dangerous because it releases carbon monoxide!

52.3 A PROGRESSION OF ANALYSIS FOR TROUBLESHOOTING

One way of increasing speed and accuracy when troubleshooting is to try to eliminate possible problems with each test made. For example, on a no-heat service call, many technicians will turn the fan switch to ON to see if the indoor fan comes on. If it does come on, two possible problems have been eliminated: line voltage to the furnace and control voltage from the transformer. This eliminates them as possible problems. There should be a logical reason for each test that is performed. As successive tests are made, the possibilities should narrow, eventually leading to the cause of the problem. Understanding the normal operational sequence

of the furnace is crucial. The following operational sequence works for most furnaces made today.

1. The thermostat calls for heat.
2. The induced-draft fan motor energizes.
3. The draft switch closes to prove the draft.

(a)

(b)

(c)

Figure 52-5 (a) The igniter is manually engaged by pushing the red button; (b) a spark is generated to light the pilot; (c) the pilot is lit.

4. The igniter is energized for approximately a minute.
5. The gas valve is energized.
6. The burners light.
7. The indoor blower comes on after a delay of a few minutes.

The technician can learn where to start troubleshooting by observing the system and understanding the checks the system makes along the way. For example, if the igniter is coming on, there is no need to check the draft switch because the draft switch must close before the igniter can come on.

52.4 STANDARD FURNACES

Since many thousands of standard furnaces are in residential use that were manufactured before the 78 percent AFUE minimum requirements, the service technician must be prepared to troubleshoot these units. Some important differences from the newer designs are natural-draft venting and standing gas pilots.

The sequence of operation for a standing pilot, natural-draft furnace is not complicated, but it is different from furnaces manufactured today.

The standing pilot light must be lit before the furnace can operate. The gas valve selection lever is turned to the pilot position and manually depressed so that gas will come out of the pilot burner. The pilot burner is lit with a match or igniter (Figure 52-5). The valve selection lever must be held in for a minute to allow the thermocouple to heat up enough to hold in the safety solenoid. After letting up on the valve selection lever, rotate it to the ON position (Figure 52-6).

The thermostat calls for heat and energizes the gas valve. The 24 V circuit to the gas valve passes through all the system safeties, like the limit switch. If the furnace overheats, the limit switch will de-energize the gas valve. After the burners light, the furnace heat exchanger heats up. When the fan switch senses the fan-on temperature, the fan motor is energized by the closing of the fan switch. When the thermostat is satisfied, the circuit to the gas valve is opened and the gas valve shuts down. The indoor blower continues to run, cooling down the heat exchanger. When the fan switch reaches the fan-off temperature, the fan shuts off.

TECH TIP

Standing pilots have been mostly replaced by intermittent pilots. However, the distinct advantage to a standing pilot gas space heater is that no outside source of electricity is required to operate it. Gas-fired space heaters do not have blowers. The only requirement is for the pilot to be initially lit. Depending on the BTU output, they can heat a small room. The thermostat requires no external power and will cycle the main burner valve on and off dependent on the temperature setting. This type of space heater is ideally suited for a remote camp and is often used for gas-fired fireplaces and gas-fired wood stoves. These can provide heat during a power outage when no other source of heat is available.

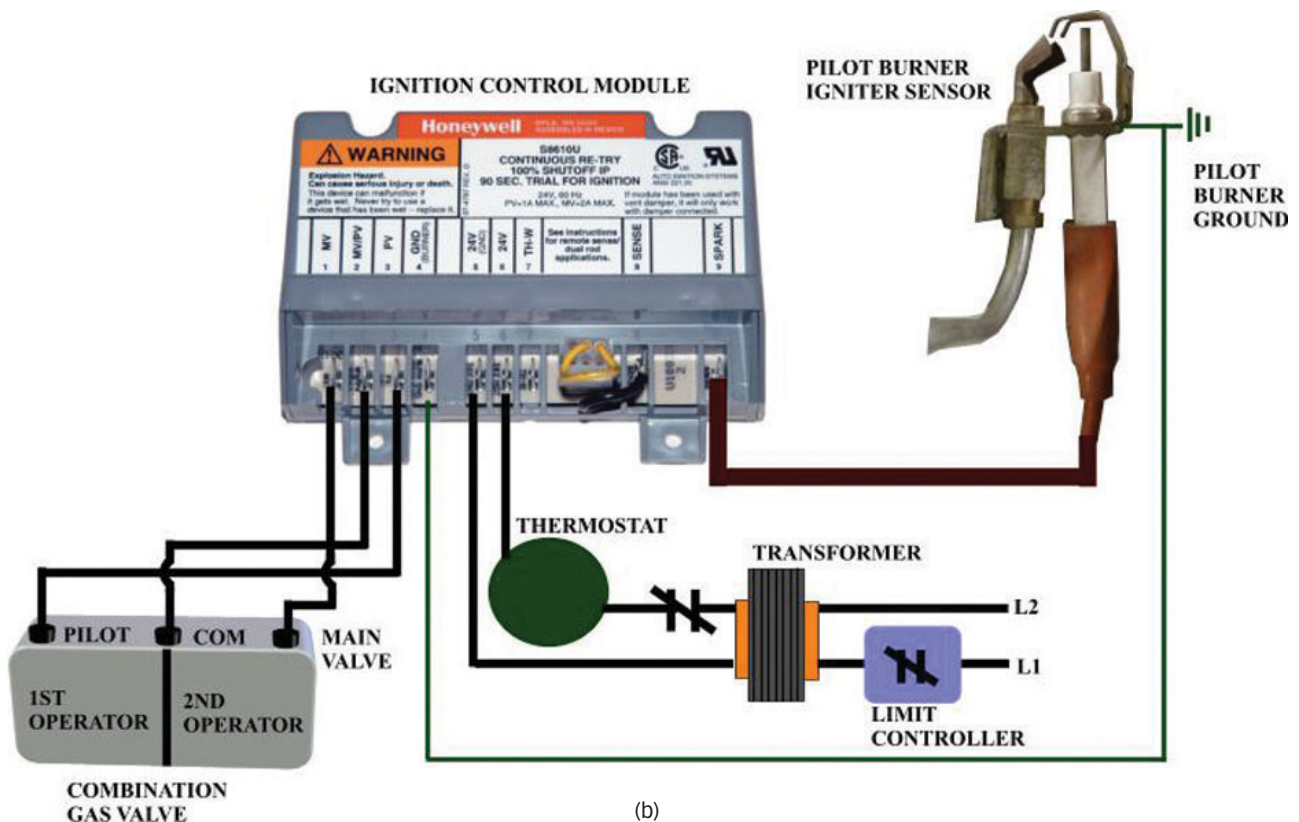

Figure 52-6 The gas valve for the standing pilot has a manual knob that must be pushed in and turned.

52.5 INTERMITTENT PILOT SYSTEMS

A typical ignition control module for an intermittent pilot system installed on a furnace with atmospheric burners is shown in Figure 52-7. This type of module can be used for different furnace configurations. As an example, if the pilot has a separate flame sensor, it would need to be connected slightly different, as shown in Figure 52-8. This type of module should not be allowed to get wet or be exposed to high humidity, corrosive chemicals, dust, grease, or excessive temperatures. The starting sequence begins with a trial for ignition. An electronic spark generator in the module produces a pulse output of over 10,000 V, and at the same time, the first main valve operator opens, allowing gas to flow to the pilot burner. If the pilot does not light or if the pilot flame current is too low and not steady, the module will not energize the main valve and the main burner will not light.

(a)

(b)

Figure 52-7 (a) Ignition control module connections; (b) ignition control module configuration for a furnace with atmospheric burners.

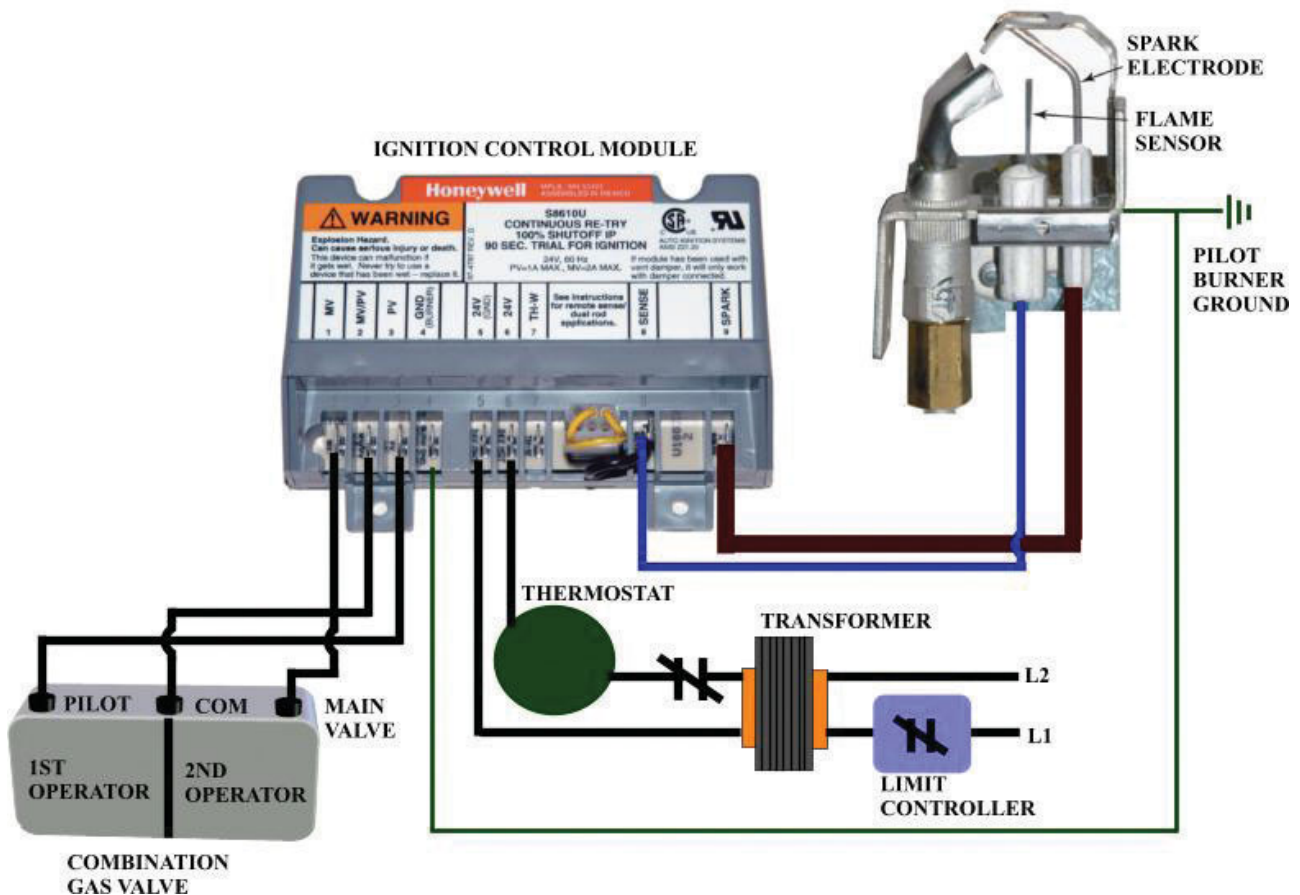

Figure 52-8 Ignition control module configuration for furnace with a separate flame sensor and atmospheric burners.

The sequence for a trial ignition will differ for a fan-assisted combustion system. In this case, there will be an air proving switch and a combustion air blower motor relay, as shown in Figure 52-9. On a call for heat from the thermostat, the blower initially starts. There will be approximately a 45-second pre-purge before the module begins the pilot ignition sequence.

Safety Lockout

The ignition spark will only continue until the timed trial for the ignition period ends. If the trial for ignition fails, then the first main valve operator de-energizes and closes flow to the pilot burner, stopping gas flow. There are different configurations for lockout.

- **Safety lockout** This can be reset by setting the thermostat below room temperature for a specific time (approximately 1 minute) or by turning off the power to the ignition module for a specific time (approximately 1 minute).
- **Safety shutoff with continuous retry** If the ignition trial initially fails, the module will restart the ignition sequence over again after a time delay period (approximately 5 minutes).

TECH TIP

The ignition process may repeat several times before lockout occurs. Depending on the manufacturer's setup, lockout may automatically reset after an hour or more, or it may have to be reset manually. Both the automatic and manual ignition lockouts can be reset manually by turning the power off for a few seconds, then powering up again.

Pilot Appearance

The pilot flame should be blue and steady, and it should envelope $\frac{3}{8}$ to $\frac{1}{2}$ in of the flame rod (Figure 52-10). A flame that is too small can be caused by a lack of gas. This would result from a clogged orifice filter, clogged pilot filter, low gas supply pressure, or an incorrect pilot adjustment (pilot set at minimum). Examples of incorrect pilot flames are shown in Figure 52-11.

A lazy yellow flame can be caused by a lack of air. This could result from a large orifice, dirty lint screen, dirty primary air opening, or an incorrect pilot adjustment. A waving blue flame is caused by an excessive draft at the

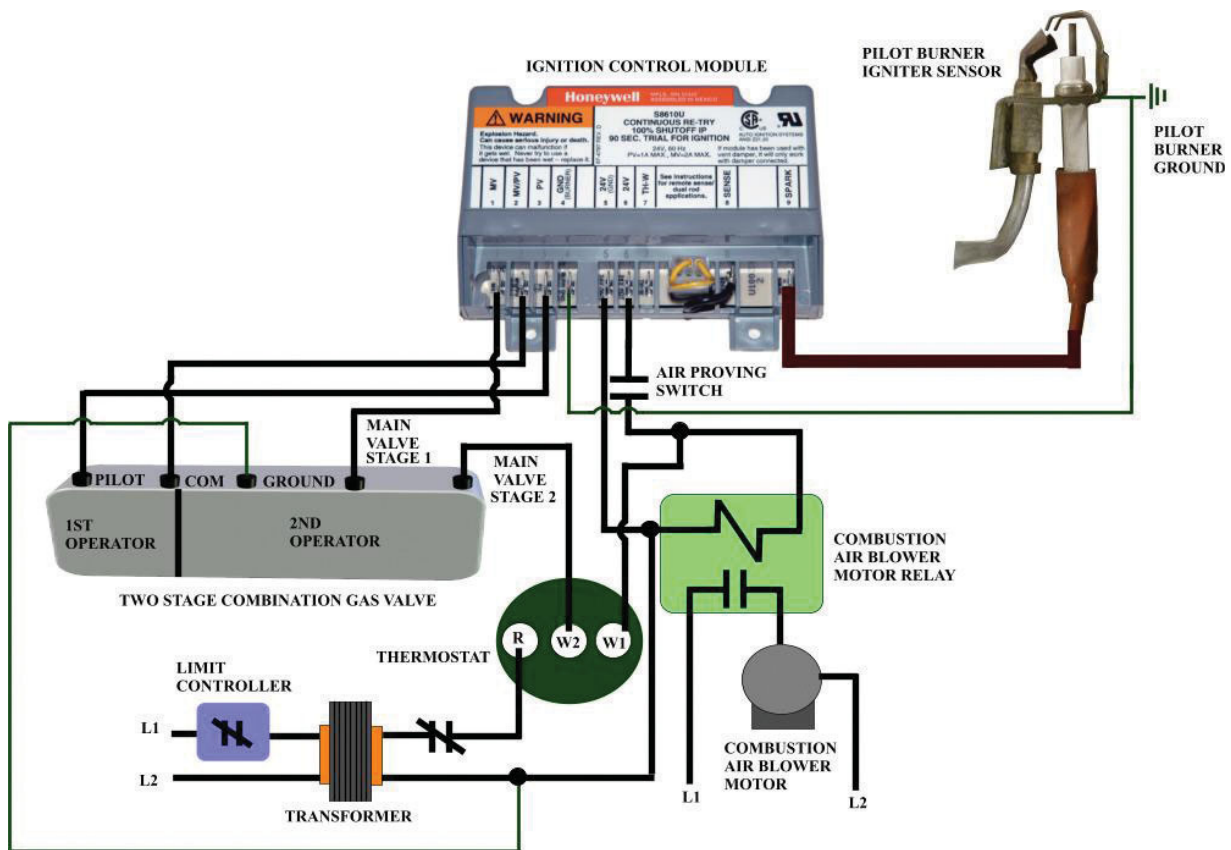

Figure 52-9 Ignition control module configuration for a fan-assisted furnace.

pilot location or recirculating products of combustion. A noisy, lifting, blowing flame is caused by high gas pressure. A hard, sharp flame is caused by high gas pressure or an orifice that is too small.

Ignition Trial Successful

If the pilot flame is established, then the flame rectification circuit is completed between the sensor and the burner ground. The spark is shut off and the second main valve operator is energized and opens the main valve to allow gas to flow to the burner, where it is ignited by the pilot.

Figure 52-10 Pilot flame envelopes $\frac{3}{8}$ to $\frac{1}{2}$ in of the flame rod.

Figure 52-11 Incorrect pilot flames.

52.6 DIRECT SPARK IGNITION SYSTEMS

Outdoor furnaces and packaged units with gas heat often use direct spark ignition (DSI) systems. A direct spark ignition system does not have a pilot light. Instead, DSI systems use a spark to ignite the main burners. They consist of a DSI control board (Figure 52-12), a sparker (Figure 52-13), and a flame sensor (Figure 52-14). Flame rectification is used to

Figure 52-12 DSI Control.

Figure 52-13 Sparker on DSI system.

Figure 52-14 Flame sensor on DSI system.

sense the presence of flames because it is the only method that is fast enough. Since gas is flowing to the main burners, the gas must be shut down quickly if flames are not sensed.

Operating Sequence

Understanding the operating sequence of a Direct Spark Ignition System (DSI) will make troubleshooting it much easier. First the draft inducer fan is energized. It runs for 30-45 seconds to perform a pre-purge to vent any accumulated gas or combustion products. After the pre-purge, the spark igniter and main gas valve are energized simultaneously. Typically ignition trials last 3-5 seconds. If flames are not sensed, the gas valve is shut off, the draft blower continues and another ignition trial occurs after a short purge period. Most DSI controls lock out after 3-5 unsuccessful attempts. If flame is established, the gas valve remains energized and the spark igniter is de-energized. After a time delay, the indoor blower is energized.

Nothing Operates

If nothing happens on a call for heat, first check the thermostat setting, power to the unit, and control voltage. The first thing that must come on is the draft fan. Test to see if the draft fan is receiving power to determine if the problem is the draft fan or the circuit to the draft fan.

Only the Draft fan runs

Draft fan operation is sensed by a pressure switch (Figure 52-15), a centrifugal switch, or a hall effect switch. If the fan is operating and the switch is not closing, make sure the draft fan is actually creating a draft. Sometimes the inducer fan rusts out or disintegrates. The motor operates but there is no fan to create a draft. The switch may be bad, or the hose to the draft switch may be loose or cracked.

Draft Switch Closing but No Ignition

When troubleshooting a DSI system that is not igniting, try to determine if the igniter is sparking. For safety, turn the gas off, call for heat, and listen for the "clicking" sound of the

Figure 52-15 Draft sensing switch.

spark. If you do not have spark, check the power to the DSI control, the sparker wire and connections at both the board and at the igniter. A break in the insulation or the wire can prevent sparking. Check the grounding of the control and the unit. Check all safeties such as limits and roll out switches. An open safety can prevent the board from trying to spark.

Sparking but No Ignition

If the igniter is sparking, try to determine if the gas valve is energized. For safety, this can be done with the main gas valve closed. You need to check the voltage to the gas valve during an ignition trial. You need to have your meter ready to read voltage because you only have a few seconds to take the reading. Leads with Alligator clips are useful. If the valve is not receiving voltage but the igniter is sparking, either the ignition board is bad or there is a bad connection between the board and the valve.

If the valve is receiving voltage, set two manometers up to read the pressure entering and leaving the valve, turn the gas on, and call for heat. If the valve has the correct gas inlet pressure, there should be outlet pressure when the valve is energized. If not, the valve is bad.

Flames Ignite But Go Out

If the flames light but extinguish, the flame rectification circuit is not sensing the flames. This can be due to poor flame sensor positioning, poor ground, a defective flame sensor, or a defective ignition board. The flame sensing circuit can be checked using a multi-meter with a DC microamp setting. The meter must be wired in series with the circuit. The wire to the flame sensor is removed, the red meter lead connects to the wire and the black meter lead connects to the flame sensor, putting the meter in series between the ignition board and the flame sensor, Figure 52-16. When the flame touches the flame sensor, a DC microamp signal

Figure 52-16 Multimeter is placed in series to check the microamp signal.

of 2-50 microamps indicates that the flame sensing circuit is working.

52.7 HOT SURFACE IGNITION SYSTEMS

Hot surface ignition systems are the most common among furnaces today. Like the DSI systems, hot surface systems do not have a pilot light; they light the main burners. The primary difference is that hot surface ignition systems use igniters that heat up instead of a spark. The spark on most DSI systems is very small, and its location is critical. Hot surface igniters are large in comparison, so their placement is not as critical. It is easy to tell when an igniter is working because it becomes so bright that it is hard to look at, Figure 52-17.

Operating Sequence

Understanding the operating sequence of a Hot Surface Ignition System (HSI) will make troubleshooting it much easier. The operating sequence is similar to a DSI system with the addition of a time delay to wait for the hot surface igniter to heat up. First the draft inducer fan is energized. It runs for 30-45 seconds to preform a pre-purge to vent any accumulated gas or combustion products. After the pre-purge, the draft switch looks to see if there is a draft. After the draft switch closes, the hot surface igniter is energized for 30-60 seconds to allow it to heat up. The gas valve is then energized and the flame sensor looks to see if flame has been established. Typically ignition trials last 3-5 seconds. If flames are not sensed, the gas valve is shut off, the draft blower continues and another ignition trial occurs after a short purge period. Most HSI controls lock out after 3-5 unsuccessful attempts. If flame is established, the gas valve remains energized and the blower is energized after a time delay.

Nothing Operates

If nothing happens on a call for heat, first check the thermostat setting, power to the unit, and control voltage. The first thing that must come on is the draft fan. Test to see if the draft fan is receiving power to determine if the problem is the draft fan or the circuit to the draft fan.

Figure 52-17 Hot surface igniter in operation.

Only the Draft fan runs

Draft fan operation is sensed by a pressure switch. If the fan is operating and the switch is not closing, make sure the draft fan is actually creating a draft. Sometimes the inducer fan rusts out or disintegrates. The motor operates but there is no fan to create a draft. The switch may be bad, or the hose to the draft switch may be loose or cracked.

Draft Switch Closing but Igniter Not Glowing

It is easy to tell if the igniter is working because it gets red hot and then glows. If you cannot see the igniter, an amp reading will tell if it is operating. Igniters can be checked using an ohm meter. A bad igniter will ohm out open—an infinite resistance. The voltage to the igniter should normally be 70-120 volts depending on the control.

Igniter Glowing but No Ignition

If the igniter is glowing, try to determine if the gas valve is energized. Use the same procedure as outlined for DSI controls.

Flames Ignite But Go Out

If the flames light but extinguish, the flame rectification circuit is not sensing the flames. Use the same procedure as outlined for DSI controls.

Induced Draft Blower and Fan Operating Constantly

Many HSI controls will operate both the draft fan and the indoor blower if one of the limits or roll out switches opens. Typically all the safeties are wired in a big series loop that wires to the control board. If any safety opens, the board shuts down the gas and the igniter and operates both fans to cool the furnace down.

52.8 MICROPROCESSOR FURNACE CONTROLS

Many of the newer furnaces use microprocessor controls and circuit boards. Keep in mind that while many controls may appear identical, timing sequences and programmed delays can vary between furnace manufacturers. Never substitute controls without the manufacturer's consent, as it can result in very dangerous conditions.

One helpful feature of the solid-state control system is its ability to diagnose its own service problems. For example, a component test is available that allows all components, except the gas valve, to run for a short period of time to reveal any service problems or indicate a component failure. Some advanced boards can store a history of the last several fault codes. This is especially helpful when diagnosing intermittent problems.

SERVICE TIP

Many of the components found in medium- and high-efficiency furnaces contain computer chips. These chips are protected from accidental damage as a result of a minor static discharge. However, they may not withstand the current from an improperly installed jumper. Before jumping terminals as part of board troubleshooting, make certain that you are following the correct procedure.

52.9 GENERAL PROCEDURES

A suggested progression of analysis for troubleshooting starts with identifying the common categories of complaints or problems, then the possible problems in the system, followed by the symptoms and causes of specific problems. Causes can be either electrical or mechanical and related to the use of gas equipment.

TECH TIP

Before beginning the actual testing or troubleshooting of a unit, take a few moments to check the system visually. Look for indications of arcing, burned or overheated wires, loose wires, or other easily visible mechanical signs of damage. Often the few minutes spent checking the system over can result in identifying the problem more quickly.

The categories of complaints or problems fall under the following headings:

1. Entire system operation
2. Unit operation
3. Burner operation
4. Blower operation
5. Heat exchanger complaints
6. Cost of operation
7. Noise

52.10 DIAGNOSTIC FLOW CHARTS

Many technicians find it helpful to use a troubleshooting flowchart. The first thing to check is always the power supply. Is proper power being supplied to the unit? A voltmeter is a handy tool to use in checking the power supply. The second item to check is the thermostat. Is the thermostat calling for heat? If both of these conditions are satisfactory, the wiring diagram should be referenced. Prior to cycling power or removing a door that would de-energize the unit, inspect the furnace for the presence of a fault light designed to give the technician insight into the cause of a shutdown or fault. Many times, cycling power will cause these valuable data to be lost.

TECH TIP

Manufacturers have done extensive research into the diagnostic testing of equipment. They provide this material in the form of flowcharts or troubleshooting tables. Using the manufacturer's troubleshooting information will make it much easier to locate and repair problems.

52.11 GAS SYSTEM PROBLEMS

Many of the solutions to problems are not always evident when the cause is determined. The following list of problem categories includes additional information regarding some of the remedies that can be tried.

- Control transformer burned out
- Pilot outage
- Gas valve stuck open or closed
- Improper heat anticipator setting
- Cycling on the limit control
- Fan control settings
- Improper burner adjustment
- Improper combustion air supply
- Improper venting
- Blower drive
- Expansion noise in heat exchanger

1. **Control transformer burned out** An ohmmeter should be used to determine whether the primary or the secondary of the transformer is burned out. The cause is probably an overload in the secondary, which needs to be corrected before the transformer is replaced. If the overload cannot be reduced, a larger transformer must be used for the replacement.
2. **Pilot outage** One of the most common causes of pilot failure is improper impingement of the flame on the thermocouple. Sometimes the pilot is extinguished by the gas burner during lighting. It is actually blown out by the burner flame. To correct this, it is often necessary to reposition the pilot to a more favorable location.
3. **Gas valve stuck open or closed** A malfunctioning gas valve should be replaced.
4. **Improper heat anticipator setting** The anticipator should be set at the amount of current traveling in the control circuit when the unit is operating. The current can be measured using a multiplier coil and a clamp-on ammeter.
5. **Cycling on the limit control** Occasionally a limit control will weaken and lower the operating range of the control. The normal range is to cut off between 140°F for a counterflow unit to 160–220°F on upright and horizontal units. If the control is cycling at a lower range, replace it.
6. **Fan control settings** Almost all gas-fired units operate best with fan control settings of 125–130°F fan on and 100–105°F fan off. If the unit blows cold air on start-up, the fan-on temperature can be changed to 145–150°F.

Figure 52-18 Primary and secondary air supply to the gas burner.

7. **Improper burner adjustment** A properly adjusted burner will have approximately 40 percent of the combustion air mixing with 100 percent of the gas in the burner and 60 percent of the air mixing with the flame above the burner to complete the combustion process. Figure 52-18 shows a typical burner arrangement.

The proper setting of the primary air quantity is the beginning step in producing high unit operating efficiency. Improper setting of the primary air shutter can contribute to pilot outage by producing extinction flashback, called *extinction pop*.

As the gas is emitted from the orifice, it expands and hits the proper place in the throat of the burner venturi. This produces maximum pull of primary air into the burner. Setting the burner for the correct flame condition will mean a minimum opening in the primary air control.

Figure 52-19a shows the size of the opening in an ordinary butterfly air control. When the burner and orifice are aligned properly and the burner is working correctly, a small opening in the primary air control will produce the soft blue flame that gives best overall unit performance (Figure 52-19b).

An all-blue sharp flame is one that is receiving too much primary air. This means that there is less radiant heat to heat the lower portion of the heat exchanger. Also, the excess air drives the flame products from the heat exchanger before good transfer of heat occurs from the flue product to the heat exchanger. Flue product temperatures rise and the unit efficiency drops.

On the contrary, if the primary air is reduced too much, heavy yellow tips of improperly burning carbon are produced. These result in much lower temperatures, and less heat is produced. Therefore, the unit efficiency will drop. In addition, the carbon will release from the flame and collect in the heat exchanger, to causing sooting and plugging of the flue passages.

TECH TIP

Soot is most often caused by improper fuel/air adjustments. However, if the flame impinges on internal metal parts of the furnace, then heat can be pulled out of the flame rapidly enough to retard proper combustion. Flame impingement can result in carbon forming. An example of carbon formed as the result of flame impingement can be seen if a copper wire is held in a match flame. Within moments, black carbon will form around the copper wire as it withdraws the heat from the flame and retards the complete combustion process.

Figure 52-19 (a) Primary air control opening size; (b) soft blue flame with proper air control.

When the burner is operating, the gas/air mixture is blowing upward through the burner port at a given speed or velocity (determined by the burner design and type of gas). There is also a downward force or burning velocity, which is equalized by the gas/air outward velocity when burning is taking place. If, however, the burning velocity were to increase due to shutoff of the gas supply, the flame could approach the burner. Either the burner would absorb the heat below the combustion point and extinguish the flame or the flame would burn down through the burner port and ignite the mixture in the burner. This ignition produces the extinction pop.

Figure 52-20 Rollout, due to insufficient secondary air.

8. Improper combustion air supply Excess air is needed for proper combustion, even though changes in gas pressure, heat content of the gas, and barometric pressure may occur. Draft conditions also change with barometric pressure and wind conditions.

When a unit encounters insufficient combustion air, the flame tends to become lazy and erratic and may even roll over the edge of the burner and out the burner pouch opening. The flame will seek air. Figure 52-20 shows the effect of insufficient secondary air causing a floating flame.

9. Improper venting The mixture of gas and air produces a mixture of water, carbon dioxide, nitrogen, and excess air. All of this has to be removed from the heat exchanger. This removal process is called venting.

TECH TIP

The inside lining of a double-walled vent pipe is made of aluminum. Aluminum is used because it heats up very quickly once the furnace starts. If heavier metal were used that warmed up slower, the water vapor in the vent gases would condense inside of the flue pipe until it heated up. This condensed water would then run down and corrode the furnace and/or heat exchanger. Even with an aluminum-lined vent pipe, some condensation occurs, and in extremely cold climates enough water can be condensed to still run down to the furnace. Fortunately, in cold climates the furnace will run long enough to evaporate most of that moisture before it has a chance to cause damage. Traces of the moisture can be found around the furnace vent. Technicians may assume that water is from a leaking roof stack, but often it is just condensation.

There are two types of venting: active (power) venting and atmospheric, or passive (gravity), venting. Active venting uses a mechanical device such as a motor-driven blower to either draw flue products from the heat exchanger or to

force combustion air into the heat exchanger. The most popular type is the draw type, where the blower is mounted on the flue outlet and creates negative pressure in the outlet of the heat exchanger to get the desired combustion efficiency. Because the pressure difference is caused by mechanical power, wind and/or atmospheric conditions have little effect on the venting performance.

In atmospheric, or passive, venting, hot flue gases pass from the heat exchanger into a flue pipe, chimney, or vent stack. The driving force for a passive vent is obtained from the hot gases rising in the surrounding cooler air. The amount of force depends on the temperature of the hot gases and the height of the gravity vent. The hotter the gases and/or the higher the vent, the greater the amount of driving force or pull that is produced. Also, the greater the pull, the more secondary air is drawn through the heat exchanger.

Enough air must be drawn through to provide complete combustion as well as complete venting of the flue products. If too much air is drawn out of the heat exchanger before the correct amount of heat extraction is done, this results in higher flue temperatures and reduced unit efficiency.

If the passive vent pipe were connected directly to the flue outlet, the amount of air drawn through the heat exchanger would vary with factors like the pull of the vent stack, the wind effect on the vent stack, and outside temperature. Control of the venting rate on the heat exchanger would be impossible. Further, under some atmospheric conditions it may be possible to have a higher pressure at the outlet of the vent than the combustion process can overcome. This can produce poor combustion, with the production of CO as well as the usual products of CO₂ and H₂O.

To overcome the effect of atmospheric conditions, all units use an opening in the venting system called a draft diverter. Figure 52-21 shows four typical heating unit draft

Figure 52-21 Typical gas appliance draft diverters.

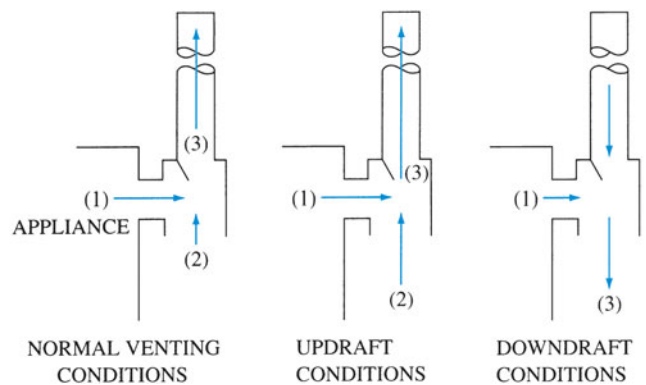

Figure 52-22 Operation of a draft diverter under various wind conditions.

diverters. These all consist of an opening from the flue outlet of the heating unit, an opening into the vent pipe, and a relief opening to the surrounding atmosphere.

Figure 52-22 shows the operation of a typical draft diverter under no-wind conditions and with updraft and downdraft conditions. The amount of flue products, the dilution air entering the relief opening, and the amount of vent gases are indicated by the length of the arrows. With normal venting, some air is pulled into the draft diverter by the pull of the passive vent. The mixture of flue products and surrounding air (called dilution air) that blows up the vent is called vent gas. The action of the draft diverter is to break the effect of the vent by introducing surrounding air and neutralizing the pull at the flue outlet. The heat exchanger then operates at approximately equal pressure from burner opening to flue outlet. The amount of air for combustion is then controlled by the flue restrictors.

If the conditions surrounding the vent stack increase the stack pull, additional air is drawn into the draft diverter to compensate for the increased pull. There is little effect on the heat exchanger performance.

Under conditions where the vent stack pull is reduced or even reversed, creating a downdraft, all combustion flue products are forced into the surrounding area. In addition, the increased pressure in the flue outlet will reduce the flow through the heat exchanger. This can cause incomplete combustion and produce odors carried by the gases and moisture produced by the combustion process. Even though no odors may result, the large amount of moisture produced in the combustion process can accumulate in the occupied area and create adverse living conditions or possible structural damage.

To check for proper operation of the vent system, use a candle placed below the bottom edge of the diverter opening. With the unit operating and up to temperature, the candle flame should bend in the direction of the opening in the diverter. If the flame is neutral, the draft is on the weak side. Possibly the vent stack is not high enough or large enough. If the candle flame bends outward, a draft problem definitely exists that must be corrected. If the vent stack cannot be lengthened or enlarged, a forced-draft unit must be installed to overcome the problem.

- 10. Blower drive** Belt driven blowers have a higher probability of vibration problems than direct drive blowers due to the additional parts involved. The most common problem is due to belt tension. It is commonly believed that the tighter the belt, the better the performance, but the opposite is true. The tighter the belt, the harder the motor has to work to get the belt in and out of the pulleys. The belt should therefore be as loose as possible without slipping on startup.

It should be possible to easily depress the belt midway between the motor shaft and blower shafts $\frac{3}{4}$ in to 1 in for each 12 in of distance between the shafts. Alignment of the motor and blower pulleys is important to keep vibration to a minimum as well as to reduce wear on the sides of the belt.

Both motor pulley and blower pulley should be checked. They should be parallel to each other and perpendicular to the shaft. A warped pulley has a visible wobble that will create vibrations. Warped pulleys should be replaced.

- 11. Expansion noise in heat exchanger** Figure 52-23 shows a four-section unit, each section composed of a right-hand and left-hand drawn steel “clamshell” welded together. The sections are then joined and welded into an assembly by fastening them to the front mounting plate and rear retainer strap. Sometimes in the welding process stresses will be set up if the two metals are at different temperatures when the bond is made. This results in expansion noises, ticking, and popping as the heat exchanger heats and cools. Most of the time, these noises are muffled by the unit casing and duct system to a level where they are not objectionable.

In extreme cases, it is possible to reduce the noises by operating the unit with the blower disconnected, allowing the limit control to turn the unit off and on. This should be done through several cycles of the limit control. Cycling on this extreme heat will cause metal to stretch beyond the normal operation range and eliminate the sound. If this does not produce satisfactory results, the only cure is to change the heat exchanger.

- 12. Oil-can effect** This effect is caused by the sudden movement of a flat metal surface where a forming stress has been left in the surface. This stress causes

the metal to have a slightly concave or convex position rather than a flat plane surface.

Temperature change will cause a stress increase in the material until the metal rapidly changes position to the opposite of its original position. This change will produce a loud bang. Ductwork is very prone to this action and must be cross-broken over any large panel areas. Unless this surface is cross-broken, it is subject to the oil-can effect. The best correction is to remove the panel and cross-break it to relieve temperature stresses.

UNIT 52—SUMMARY

When troubleshooting a gas furnace, the technician’s first responsibility is to perform a safety check. Look for visual signs of problems. After verifying that the system is safe to operate, proceed in a systematic manner. Use available resources such as troubleshooting flowcharts and diagnostic codes. Perform tests that can eliminate possible problem causes and narrow your search. Try to look for underlying causes, not just symptoms. For example: if a furnace is tripping out on the high limit, check for airflow problems. After isolating and repairing the problem, retest the system to ensure safe and proper operation.

WORK ORDERS

Service Ticket 5201

Customer Complaint: No Heat

Equipment Type: 80 Percent Mid-Efficiency

A technician responds to a no-heat call. The technician sets the thermostat to call for heat and the draft-inducer fan starts, but nothing else happens. A check of the draft switch shows that it has not closed. A check of the pressure on the hose to the draft switch reads 0 in wc. The technician removes the tube to see if it is plugged and water comes out of the tube. Rechecking the draft, it now reads 0.25 in wc vacuum. The furnace now lights and operates.

Service Ticket 5202

Customer Complaint: No Heat

Equipment Type: 80 Percent Mid-Efficiency

A technician responds to a no-heat call. The technician sets the thermostat to call for heat and the draft-inducer fan starts, but nothing else happens. A check of the draft switch shows that it has closed. A voltage check at the igniter shows that the igniter is receiving voltage but is not operating. The technician checks the resistance of the igniter with an ohmmeter, and it reads infinity. The technician replaces the igniter. The furnace now operates correctly.

Figure 52-23 Clamshell gas heat exchanger.

Service Ticket 5203**Customer Complaint: Insufficient Heat****Equipment Type: 80 Percent Two-Stage Mid-Efficiency**

A technician responds to an insufficient heat call. The technician sets the thermostat to call for high fire. The furnace lights and operates. The technician checks the voltage at the high-fire solenoid on the gas valve and reads 24 V. Next, the gas pressure is checked. It reads 1.5 in wc at the manifold and 7 in wc at the gas valve inlet. The furnace data plate reads 1.5 in low-fire manifold pressure and 3.5 in high-fire manifold pressure. The technician unsuccessfully tries to adjust the high-fire manifold pressure. The gas valve is determined to be defective and is replaced. When the system is rechecked, the high-fire manifold pressure reads 3.5 in wc.

Service Ticket 5204**Customer Complaint: Furnace Sometimes Does Not Heat****Equipment Type: 90 Percent Condensing Furnace Installed in Crawlpace**

A technician is called to look at a 90 percent condensing furnace that works sometimes and sometimes does not. The furnace is operating when the technician arrives. The customer says that he turns the heat off when he leaves for work and back on when he gets home. Occasionally on really cold days, the furnace will not come on. Yet it comes on later, usually after the outside temperature has warmed up a little. The furnace has a microprocessor control that stores fault history. The technician checks the fault history and sees that the furnace has shut down on draft safety several times. The technician notices that the drain from the condensate pump runs a long way through the crawl-space and that the pump is equipped with an overflow kill switch. The technician concludes that water is freezing in the condensate pump discharge line, causing the sump to fill and the kill switch to shut down the furnace. The technician replaces the soft plastic tubing used for the condensate pump discharge line with PVC, wraps the PVC with heat tape, and places pipe insulation over the new PVC condensate discharge line. Before leaving, the technician clears the fault codes so any faults that are stored will be after the drain fix. The mysterious cold weather shutdowns disappear. The technician checks the fault codes during the subsequent spring checkup and finds none.

Service Ticket 5205**Customer Complaint: No Heat****Equipment Type: Standing Pilot, Natural-Draft Furnace**

A technician responds to a no-heat call on an old standard furnace. The technician notices the pilot light is not burning and attempts to light it. The pilot light will light, but it will not stay lit. The technician checks the

millivoltage output of the thermocouple, reads 0 mV, and determines that the thermocouple is defective. The technician changes the thermocouple, lights the pilot light, and the furnace operates correctly.

Service Ticket 5206**Customer Complaint: No Heat****Equipment Type: Standing Pilot, Natural-Draft Furnace**

A technician responds to a no-heat call on an old standard furnace. On a call for heat, the main burners light. After burning for several minutes, the burners shut down. The indoor blower never comes on. The technician checks voltage to the blower motor and finds 0 V. The technician observes that the fan switch has rotated past the fan on the cut-in point and decides to check the fan switch next. Entering the fan switch is 120 V, but leaving is 0 volts. The technician concludes that the fan switch is defective. The flames had shut down on limit since the fan never came on. The fan switch is changed and the system rechecked. This time the fan comes on about 3 minutes after the burners light and the burners stay lit.

Service Ticket 5207**Customer Complaint: Carbon Monoxide Alarm****Equipment Type: 80 Percent Mid-Efficiency Upflow Replacement Furnace**

A technician is sent to look at a 1-year-old mid-efficiency replacement furnace. The original installing contractor is no longer in business. The furnace is installed in the basement and connected to the old vent system. The technician observes that the old vent is a 7-in single-wall vent and the flue collar on the new furnace is 4 in. Streaky rust stains appear on the bottom of every vent joint. The flames in one tube are visibly different from the others. The flames in that tube blow all around when the indoor blower comes on. The technician shuts down the furnace, removes the burner from that tube, and takes a closer look at the tube. There is a lot of rust and a hole at the back of the tube. The technician concludes that the heat exchanger has rusted out as a result of condensation in the oversized single-wall vent. The technician recommends that the heat exchanger be replaced and a new correctly sized double-wall vent run.

Service Ticket 5208**Customer Complaint: No Heat****Equipment Type: 90 Percent Condensing Furnace with Combustion Air Piped In**

A technician responds to a no-heat call. The induced-draft blower starts on a call for heat, but nothing else happens. The technician checks the draft switch and finds that it has not closed. Next, the vent pressure is checked and found to be -0.3 in wc in the combustion air pipe and

+0.05 in wc in the vent pipe. The technician checks the ends of the air intake and vent pipes and notices leaves and grass in the end of the air intake pipe. Closer inspection reveals a bird's nest in the air intake. The technician removes the bird's nest and checks the vent screen at the furnace, where a dead bird is found. The furnace operates correctly after removing the dead bird and bird's nest.

Service Ticket 5209

Customer Complaint: No Heat, Fan Runs Continuously

Equipment Type: 90 Percent Condensing Furnace

A technician is sent to a no-heat call on a high-efficiency furnace. Upon arriving, the furnace fan and combustion blower motor are running even though the thermostat is turned off. The technician checks the voltage at the W terminal and finds 0 V. The diagnostic light is flashing a code that indicates the system shut down because of an open limit switch. The technician checks the resistance of the limit switch and it is indeed open, even though it is not hot. The technician replaces the limit switch and checks the air filter. The air filter is completely blocked. Because the filter is so dirty, the technician decides to check the underside of the recuperative coil. The condensing recuperative coil is checked after removing the blower; it is matted with dirt and animal hair. The coil is cleaned and the blower replaced. The technician explains that blocked airflow from the dirty filter and coil made the furnace cycle on the limit and eventually killed the limit switch. The customer is advised that the air filter needs changing regularly, at least once a month, or the problems will repeat.

UNIT 52—REVIEW QUESTIONS

1. What is the one advantage of a standing pilot for a gas-fired space heater?
2. List the general sequence of operation for an induced-draft furnace.
3. What happens if the pilot fails to light during a trial ignition?
4. List the seven categories of complaints with gas furnaces.
5. What is the purpose of the draft diverter on natural-draft units?
6. What is an indication of too much gas at the burners?
7. What is an indication of too much primary air?
8. What is an indication of too little primary air?
9. What happens if there is improper venting of the furnace?
10. What is a safety lockout?
11. A waving blue pilot flame can be caused by what?
12. How does the trial ignition period differ between a fan-assisted furnace as compared to a furnace with atmospheric burners?

Use Table 52-1, Gas Systems Problems, to answer the following questions.

13. What are some probable causes of noise and vibration?
14. What causes rollout of burner flames?
15. What are some possible causes of burner flashback?
16. What can cause the blower to come back on for a short time after cycling off?
17. What are some possible causes of delayed ignition?
18. What can cause soot accumulation on the heat exchanger?
19. On some furnaces, little pops and pings can be heard before the blower comes on. What causes this noise?
20. A gas burner is noisy and the flames are lifting off the burner. What is the most likely cause?

UNIT 53

Oil-Fired Heating Systems

OBJECTIVES

After completing this unit, you will be able to:

1. list the grades of fuel oil and compare their properties.
2. discuss the types of nozzles available.
3. explain the operation of a fuel oil burner.
4. list the types of oil furnaces and boilers available.
5. compare the efficiency ratings of different types of oil furnaces.
6. explain the operation of oil furnace primary controls.

53.1 INTRODUCTION

Oil is still a popular form of heat in colder areas of the country such as the Northeast, which accounts for approximately 82 percent of the total usage. Today, manufacturers offer a wide array of choices in oil heat. These designs include condensing furnaces with efficiencies reaching 95 percent, furnaces with firing rates as low as 50,000 BTU/hr, two-stage residential furnaces, mid-efficiency noncondensing furnaces with efficiency ratings reaching 89 percent, and sealed combustion furnaces.

53.2 FUEL OILS

Fuel oils are mixtures of hydrocarbons made of long hydrocarbon chains derived from crude petroleum by distillation. Several different grades of fuel oil are available. Oil is divided into grades according to the oil characteristics, including viscosity, flash point, pour point, water and sediment content, carbon residue, and ash. The oil grades are classified according to their varying combinations of distillates and residuals. A distillate evaporates at relatively low temperatures. Light distillates are clear and will pour like water at normal room temperature. Residuals are what remain at the end of the distillation process. Residuals are black and tarry in appearance with the consistency of toothpaste at room temperature. Distillates are made of shorter carbon chains than residuals and have a lower heating capacity, but they are easier to store, pump, atomize, and burn. Oil grades range from 1 to 6, with 1 being 100 percent light distillates and 6 being nearly 100 percent residuals.

Oil Viscosity

Viscosity is a measure of how fast oil flows. A high viscosity number means that the oil is thicker and flows slowly, while a low viscosity number means that the oil is thinner and flows more readily. Oil's viscosity determines whether the fuel oil must be heated for it to flow. Table 53-1 shows the viscosity of several grades of fuel oil over a range of temperatures.

Table 53-1 Properties of Fuel Oils.

SERVICE TIP

All heating oil has a very distinctive odor. You must be very careful when working in residences not to contaminate the residence property with oil. Careless work habits can result in the home smelling of oil for days after a technician leaves. Often oil-fired furnaces are located in basements, some of which do not have outside access. If it is necessary for you to access the system through the residence, you should wear paper shoe covers as you enter and leave the residence and each time you enter and leave the basement. In addition, you must clean your hands thoroughly before entering the residence to adjust the thermostat, set dampers or vents, and any other such service.

Oil Grades

Grades 1 and 2 are the grades of fuel oil primarily used for comfort heating applications. Both contain high quantities

of carbon and hydrogen with traces of sulfur. The carbon content for these fuel oils ranges from 84 percent to 86 percent, with a maximum of 1 percent sulfur. The sulfur content of fuel oils is kept as low as possible to reduce air pollution.

Grade 1 fuel oil is considered premium quality. It is used in room space heaters, which do not use high pressure burners and depend on gravity flow, thus the need for the lower viscosity. Grade 2 oil is the standard grade heating oil sold. Grade 2 oil is used in equipment that has pressure atomizing, which includes most forced-air furnaces and boilers. The heating value for grades 1 and 2 oil falls in the range of 135,000 to 142,000 BTU/gal.

TECH TIP

It is often assumed that because heating oils are thicker than water they are heavier than water. This is not true. Oil floats on water. Although it is thicker than water, it is less dense. Most heating oils range between 6.8 and 7.2 lb/gal, compared to water, which weighs 8.3 lb/gal.

53.3 TYPES OF OIL-FIRED HEATING SYSTEMS

Oil fired heating systems can be categorized as either being warm air furnaces or boilers. Oil fired warm air furnaces heat the air using a heat exchanger, much like a gas furnace. The term boiler is used when water is heated instead of air. There are both steam and hot water boilers. Low pressure boilers have a working pressure of up to 15 psi steam and/or up to 160 psi water pressure at a maximum of 250°F operating temperature. Medium and high pressure boilers operate above 15 psi steam and/or over 160 psi water pressure at temperatures above 250°F. Today most oil-fired boilers used for residential heating are low pressure and do not convert the water to steam but instead are specialized hot water heaters.

Oil-Fired Boilers

Many older oil-fired heating systems were used for making low-pressure steam, thus called boilers. This steam was sent to radiators located in the living spaces. The radiators gave off heat and the steam was condensed back to water by a steam trap at the outlet of the radiator before being returned to the boiler. In this way the latent heat of the steam was transferred to the living space. Today most oil-fired boilers used for residential heating do not convert the water to steam but instead are specialized hot-water heaters. Figure 53-1 shows a typical oil-fired hot-water boiler. The hot water produced by the boiler is circulated through radiant baseboard heaters and radiant heating floor systems located in the living spaces.

Waste Oil Furnace

One product that is unique to oil-fired systems is the waste oil furnace. These are warm-air furnaces that are specifically

Figure 53-1 Hot-water oil-fired boiler.

designed to burn waste oil. Waste oil burners are particularly attractive to companies that generate waste oil. Normally, the company would have to pay to dispose of the waste oil. By using waste oil as fuel, the company not only saves on disposal costs but gets free heat in the bargain. Most modern recently manufactured oil burners are approved for use for B5 or lower grades of biofuels. However, older oil burners may need to be replaced or upgraded with all involved components to be compatible. B5 is a blend of biomass and petroleum diesel. Biomass consists of organic materials such as vegetable oils and animal fats and is a source of renewable energy. Figure 53-2 shows a waste oil furnace.

Oil-Fired Warm-Air Furnaces

Oil-fired warm-air furnaces heat the air using a heat exchanger, much like a gas furnace. Oil-fired forced-air furnaces are designed in five basic configurations:

- Upflow
- Downflow (counterflow)
- Horizontal
- Lowboy
- Multiposition models

These configurations describe the airflow through the furnace. Air travels up in an upflow furnace, down in a downflow furnace, and horizontally (left or right) in a horizontal furnace. Lowboy furnaces have two sections side by side, as do horizontal furnaces; but the air goes in the top of the furnace, makes a 180° turn as it goes through the furnace, and then leaves out the top of the furnace. Lowboy furnaces are built low in height to accommodate areas where headroom is minimal. These furnaces are approximately

Figure 53-2 Waste-oil furnace. (Photo courtesy of Clean Burn)

4 ft high, providing for easy installation in a low-ceiling-height basement. Blowers for lowboy furnaces are typically belt driven. A multiposition furnace can be used in more than one configuration.

53.4 OIL FURNACE EFFICIENCIES

Oil furnaces are available in standard efficiency, mid-efficiency, and high-efficiency condensing models. Older-design oil furnaces had combustion efficiencies of around 60 percent. Added to this is the heat lost through the large amount of air required for combustion air and dilution air. Taking this additional heat loss into account, they perform no better than 50 percent efficiency overall. Most new “standard” oil furnaces now use high-pressure burners that use a fuel pump to pressurize the oil to 100 psig or more. These operate with efficiencies closer to 80 percent, but the losses from combustion and dilution air are still present.

Many mid-efficiency furnaces, depending on their design and application, use high-pressure burners along with an increased combustion supply-air pressure. With this design, the burner flame is held very close to the face of the combustion head and the flame is smaller and more compact than with older burners. This type of burner design is referred to as flame retention and is the standard for most burners today.

With flame-retention burners, the increased combustion supply-air static pressure will push the exhaust gases up and out the chimney so a barometric damper might not be required. An advantage to this is the loss from dilution air is eliminated. The main determination for a barometric damper is the chimney. If the draft is excessive, the system may still require a barometric damper even with a high-pressure burner. Some furnaces add a sealed combustion chamber, so all the combustion air comes from outside. These furnaces operate with efficiencies of 83 to 89 percent.

Both mid-efficiency and high-efficiency furnaces are available in two-stage models that have a low and high firing rate. This improves the overall furnace efficiency by reducing the furnace cycling and extending the run times.

In the past, the number of sizes available for oil-burning furnaces was limited. Most furnace lines started big and got bigger. Offerings are more varied today, both in terms

Table 53-2 Oil Furnace Models.

Firing Rate	Efficiencies	Configurations
50,000	98%	Horizontal, unit heater
70,000	83%	Upflow
75,000	98%	Horizontal, unit heater
90,000	84%	Horizontal, upflow, downflow, lowboy
100,000	94%	Horizontal, unit heater
105,000	83%	Horizontal, upflow, downflow, lowboy
120,000	83%	Horizontal, upflow, downflow, lowboy
125,000	92%	Horizontal, unit heater
140,000	84%	Horizontal, upflow, downflow, lowboy
150,000	98%	Horizontal
200,000	94%	Horizontal
250,000	92%	Horizontal

of size and efficiency. Table 53-2 lists some examples of models available from one manufacturer.

53.5 OIL-FIRED CONDENSING FURNACES

The combustion products from an oil furnace contain only half as much water as the combustion products from a gas furnace. Since this lowers the dew point, the combustion gases from an oil furnace can be cooled further before condensation starts to take place. Therefore, mid-efficiency oil furnaces are less likely to condense water in this efficiency range as compared to gas furnaces, although this is subject to the furnace application and the operating environment.

The high-efficiency furnaces rated in the 90–95 percent efficiency range condense water out of the vent gases using a stainless steel recuperative secondary coil. The combustion gases pass through this stainless-steel recuperative

Figure 53-3 High-pressure atomizing gun-type oil burner.

secondary coil before traveling out the vent. Building a reliable condensing oil furnace can be somewhat of a challenge. This is because there is less latent heat to capture with only half as much water in the combustion gas of an oil furnace as compared to a natural gas furnace. Also, oil has considerably higher sulfur content, so the condensate is more acidic than the condensate from condensing gas furnaces. This means that the condensing recuperative secondary coil must be more resistant to corrosion. Despite these obstacles, there are over 300 furnaces listed by the Department of Energy as Energy Star furnaces. These furnaces have efficiencies in the range of 90 to 95 percent.

53.6 OIL BURNERS

The high-pressure atomizing gun burner shown in Figure 53-3 is the type used on most residential and small commercial oil-fired heating systems. Traditional high-pressure oil burners will burn with a yellow flame, as shown in Figure 53-4. High-pressure oil burners have the following components:

- Oil pump
- Air blower

Figure 53-4 Oil burner flame.

- Electric motor
- Ignition transformer
- Blast tube, with nozzles and ignition system
- Primary control

The burner illustrated in Figure 53-5 shows a cutaway view of the internal construction of a burner assembly. The pump and blower are driven from a common motor shaft. Oil is pumped through the oil burner nozzle and ignites as it passes from the burner head into the combustion chamber.

Flame Retention Burners

In a flame-retention burner, the air flow is a swirling pattern that recirculates combustion products for a more complete mixing of the fuel and air. Air from the combustion chamber

Figure 53-5 Cutaway view of the internal construction of an oil burner.

Figure 53-6 (a) Ragged flame pattern of standard burner; (b) uniform flame pattern of flame-retention burner.

is sucked back toward the burner and pulls the flame back with it. The flame stabilizes closer to the burner head and produces a more uniform flame pattern (Figure 53-6). Flame-retention burners have lower smoke levels and higher efficiencies than standard burners.

Primary air passes through the center opening, where the oil from the nozzle is sprayed (Figure 53-7). The secondary air passes through slots in the flame-retention ring

(Figure 53-8). This secondary air helps to keep the burner head clean and free of carbon and by its spinning action also helps to pull the flame back toward the flame-retention ring. Tertiary air ensures that all of the fuel oil, even in the surrounding outer edges of the spray pattern, will be burned. A variable burner head allows for adjustment either back or forth to change the tertiary opening to allow fine-tuning of the burner.

Figure 53-7 (a) Cutaway view of an oil burner showing primary, secondary, and tertiary air flow; (b) air flow through the burner head.

Figure 53-8 Slots cut into flame-retention ring to provide a path for the secondary air.

Burner Blower

The burner blower includes a centrifugal wheel mounted on the motor shaft (Figure 53-9). It furnishes air through the blast tube, which produces air/fuel turbulence for proper mixing and combustion. The amount of air is controlled by sliding an air shutter or air band on the blower housing section, as shown in Figure 53-10.

Oil Pump

The oil pump is a positive-displacement gear type (Figure 53-11) and is driven by the same motor that also drives the blower. The normal discharge pressure setting is 100 psi. This can be adjusted to as high as 200 psi because some burners are designed for higher oil pressures. However, always refer to the manufacturer's specifications for recommended pump pressures before attempting to change the pressure setting. The oil pump delivers more oil than the burner can use. The extra oil must either be bypassed internally in the pump or sent back to the tank through a separate oil return line. Thermal safety shutoff valves are used in the oil piping supply line (Figure 53-12).

Ignition Transformer and Electrodes

Ignition is provided by a high-voltage electric spark. The spark is provided by electrodes that are positioned so that the arc between them passes just above the oil and air mixture (Figure 53-13). However, the oil should not touch the electrodes, just the spark from the electrodes. The spark can either operate all the time the burner is operating, or it can be shut off after the flame is proved. The 8,000–15,000 V AC for the spark is provided by the ignition transformer, which is located on top of the burner housing (Figure 53-14).

Figure 53-10 The sliding air shutter can be positioned to allow for more or less air flow to the blower wheel.

Figure 53-11 Typical oil pump.

Figure 53-12 Thermal safety shutoff valve.

53.7 OIL BURNER NOZZLE SPRAY PATTERNS

Nozzles are described by their individual physical characteristics. These characteristics are the spray angle, the spray pattern, and the gallons per hour that pass through the nozzle at a given pressure (Figure 53-15). The nozzle is responsible for atomizing the fuel oil. The nozzle has an orifice that is factory bored to produce the correct firing rate and must not be altered or changed in any way. Under high pressure, the oil is atomized into fine droplets and mixes with the primary air. The mist from a nozzle makes a cone shape, with the point of the cone at the tip of the nozzle.

The spray angle describes the included angle of the sides of this cone. The spray patterns created by the nozzles tend to be listed as solid, semisolid, or hollow cone (Figure 53-16). A solid-cone spray pattern has a more or less uniform density of spray droplets throughout the cone shape. A hollow cone concentrates most of the droplets

(a)

(b)

Figure 53-14 Burner assembly showing position of ignition transformer.

Figure 53-15 (a) Various sizes and types of nozzles; (b) nozzle size is stamped on the nozzle; (c) nozzle angle is stamped on the nozzle.

Figure 53-16 Comparison among solid, semisolid, and hollow nozzle spray patterns.

Figure 53-17 Nozzle spray angles will vary for different size combustion chambers.

toward the outside of the cone, creating a hollow center in the cone. The semi-hollow core would be someplace between these two patterns.

The nozzle must be matched to the burner and combustion chamber. For example, a 30° spray pattern would be used for heat exchangers that are long and narrow, while a 90° spray pattern would be used for a more square shape (Figure 53-17). The mix of oil and air is controlled by the spray pattern of the nozzle and the air pattern of the burner. The burner air pattern and the nozzle spray pattern must be compatible for proper mixing. The oil spray should not touch the sides of the combustion chamber or the ignition electrodes.

TECH TIP

Although a nozzle appears to be a simple device, there are many different designs of nozzles. Having a nozzle that matches the burner design is crucial. Using a nozzle that does not match the burner could result in incomplete combustion and inefficient operation.

53.8 HEAT EXCHANGER

The typical oil-fired heat exchanger (Figure 53-18) is a cylindrical shell of heavy-gauge steel or cast iron in which combustion takes place. It offers additional surfaces for heat transfer from the products of combustion inside to the air around the outside of the chamber. This type of heat exchanger is called a drum and radiator. The inside, containing the flame, is called the primary surface, and the outside is called the secondary surface.

Some manufacturers add baffles, flanges, fins, or ribs to the surfaces to provide increased surface area to allow for faster heat transfer to the air passing over the surfaces.

The burner assembly is bolted to the front of the heat exchanger (Figure 53-19). The firing assembly and blast tube extend into the primary surface in correct relationship to the combustion chamber or refractory. A flame-inspection

(a)

(b)

Figure 53-18 (a) Oil furnace heat exchanger opened; (b) heat exchanger closed, top view.

port is provided just above the upper edge of the refractory. This is used to observe proper ignition, flame shape, and flame size and to measure over-fire draft for startup and service operations (Figure 53-20).

SAFETY TIP

Never open the inspection port unless the power to the furnace is off or there is a flame.

53.9 REFRACTORY

High temperatures are required in the flame area of the heat exchanger to produce maximum burning efficiency of the oil/air mixture. To obtain this high temperature, a reflective material, called the refractory, is installed around

Figure 53-19 Heat exchanger showing burner opening, inspection port, and tankless domestic hot-water heater location.

Figure 53-20 Burner flame inspection port.

the combustion area. It is an insulation type of material designed to reach white-hot surface temperatures quickly, with minimum deterioration. A refractory fire box is shown in Figure 53-21. It should be noted that caution should be taken not to damage the refractory if a vacuum cleaner is to be used for cleaning during routine service.

SAFETY TIP

Occasionally the refractory firebox on an oil furnace can be flooded with oil. When this happens, the excess oil must be removed before the furnace can be restarted. With the oil burner assembly removed, use dry paper towels or rags to absorb the remaining oil before attempting to relight the furnace. Never attempt to relight a furnace with liquid oil in the bottom of the refractory firebox. If the oil in the refractory firebox is ignited, it is very difficult to extinguish.

(a)

(b)

Figure 53-21 Oil furnace refractory.

CAUTION

Only CO₂-type extinguishers should be used on oil burner fires because they leave no residue. Dry chemical fire extinguishers will put out an oil fire, but the residue can cause an extensive and lengthy cleanup.

53.10 PRIMARY OIL BURNER CONTROLS

The primary control governs the operation of the oil burner (Figure 53-22). It responds to the signal from the thermostat and will control the start-up and run cycle. The primary control will also shut down the burner when the thermostat is satisfied or if the limit control opens. At one time, stack-type relays were the standard, but today mostly cad cell primary controls are used.

Cadmium Sulfide Cell (Cad Cell)

Flame safety is provided by a light-sensitive cadmium sulfide cell (Figure 53-23). The “cad cell” has a very high electrical resistance in the dark but a low electrical resistance when exposed to light. The cad cell senses when there is no flame because it cannot see the light from the flame. When the cad cell does not see the light of the flame, the primary control will stop the burner motor and ignition transformer, thus preventing oil from flowing into the heat exchanger. Most furnaces have a lockout system requiring the control to be reset manually before the burner can run again.

Figure 53-22 Oil burner primary control.

SAFETY TIP

Pushing the reset button multiple times can set up a potentially dangerous situation by soaking the combustion chamber with oil. Find out if the customer has already pushed the reset several times before trying to operate the furnace. Oil does not evaporate, so the oil will still be sitting in the combustion chamber even if the reset button was pushed several times the day before. If the furnace does light with a combustion chamber full of oil, the combustion chamber may not be able to contain the flames.

(a)

(b)

Figure 53-23 Cadmium sulfide (cad) cell.

Figure 53-24 Burner emergency switch.

Oil Burner Emergency Switch

The oil burner emergency switch has a red cover plate and is labeled for emergency (Figure 53-24). This is usually located at a convenient shutoff point for the customer to access. As an example, if the furnace is located in the basement, then it would be located at the top of the basement stairway. This allows the customer to shut down the furnace upon a malfunction, such as excessive smoking, without the need to enter the basement. There will also be a second disconnect switch located on or near the furnace for the technician to shut off whenever servicing the furnace.

Warm-Air Oil Furnace Fan and Limit Switch

One type of combination fan and limit control for a typical gas or oil warm-air furnace (Figure 53-25a-d) uses the power created by the rotary movement of a helix bimetal. The rotary motion comes about from the expansion and contraction of this bimetallic element. Since it is helical in shape, it turns in a circular motion, either clockwise or counterclockwise, depending on whether the furnace air is becoming hotter or cooler. The rotating cam makes or breaks the separate fan and limit electrical contacts. The control board in many newer oil furnaces operates the indoor blower on a timing circuit. These furnaces do not have a fan switch, only a limit switch.

Direct- and Reverse-Acting Aquastats

Aquastat controls are used for hot-water boilers. They maintain the boiler water at the proper temperature. There is a high-limit setting and a low-limit setting (Figure 53-26). Since these hot-water boilers are not designed to produce steam, the high limit will regularly shut off the burner at a preset temperature. This will prevent the water from

becoming hot enough to produce steam. If the thermostat is calling for heat, the circulating pump (called a circulator) will continue to operate and deliver hot water through the closed heating loop even though the oil burner is off. When the water temperature reaches the low limit, the burner will start up again so that the water temperature does not drop too low.

(a)

(b)

Figure 53-25 (a) Construction of combination fan and limit control for gas- or oil-fired warm-air furnaces; shows how twisting motion of heated helix activates switches; (b) control is located above and to the left of the burner; (see next page) (c) close-up of control; (d) close-up of helix

(c)

(d)

Figure 53-25 (Continued)**Figure 53-26** Aquastat with high-limit, low-limit, and differential adjustment.

The aquastat will also control the hot-water circulator (Figure 53-27). A direct-acting aquastat will start the circulator upon a drop in temperature. As an example, the thermostat calls for heat, the burner turns on, and the circulator starts. When this happens, the hot water is delivered from the boiler to the baseboard heaters and cold-water

**Figure 53-27** Hot-water circulating pump.

returns. Since the oil burner has just started, it will take a few minutes to warm up the heat exchanger. Because of this delay, the flow produced by the circulator to push the cold water back to the boiler will cause the temperature to drop too low.

A reverse-acting aquastat corrects this. It will start the circulator upon a rise in temperature instead of a drop. This allows the boiler enough time to heat up before the circulator begins pushing cold water back to it. This is important because many boilers also provide domestic hot water. With a reverse-acting aquastat, a person taking a shower would not be affected by a thermostat call for heat. This is because the circulator would not come on until the water temperature was high enough. If the circulator came on earlier, it would rob heat from the shower because of the resulting drop in the boiler temperature.

This drop in boiler temperature is also detrimental to high-efficiency boilers. The already low-temperature combustion gases would be even cooler. This causes even more water vapor to condense in the combustion chamber and exhaust vent than normal. The sulfur contained in the fuel oil will carry over in the combustion process, forming sulfuric oxides and mix with the water to create sulfuric acid. Not only is sulfuric acid highly corrosive, but it will also lead to a buildup of scale on the heat exchanger. The reverse-acting aquastat does not start the circulator until the oil burner raises the boiler temperature. This helps to keep the combustion gases above the dew-point temperature.

Hot-Water Boiler Auxiliary Components

An oil-fired hot-water boiler will have a low-water cut-off to stop the oil burner if the water level becomes too low (Figure 53-28). If more water is required, a pressure-reducing valve will automatically add makeup water from the building's water supply piping (Figure 53-29). This

(a)

(b)

(c)

Figure 53-28 (a) Low-water cutoff; (b) with cover off; (c) connection to the boiler.

Figure 53-29 Pressure-reducing valve adds makeup water to the boiler.

Figure 53-30 Boiler pressure-relief valve.

reducing valve for residential systems is set at 12 psi. In addition to this there will be a system-relief valve set for 30 psi (Figure 53-30).

The boiler will have a temperature/pressure gauge, as shown in Figure 53-31. Notice the boiler is shut down as the temperature reads low. The pressure on this gauge can be read in feet of water (outer scale) or psi (inner scale). The black needle pressure reading indicates approximately 12 to 15 psi. The red indicator arrow is pointing toward the set point for the pressure-relief valve at approximately 30 psi.

Figure 53-31 Boiler temperature and pressure gauge.

UNIT 53—SUMMARY

Today's oil heating systems are more efficient and adaptable than the large, inefficient furnaces from previous decades. Now oil heating systems are available in smaller, more efficient furnaces and boilers with efficiencies up to 95 percent. Two-stage furnaces, condensing furnaces, sealed combustion furnaces, oil-fired unit heaters, and furnaces designed to burn waste oil are some of the innovations in oil heat.

Fuel oil must be atomized to be burned. Because of this, oil furnaces have more parts and are somewhat more complex than gas furnaces. Oil burner components include an oil pump, a combustion air blower, a burner motor, a nozzle, an ignition transformer, electrodes, a primary control, and a cad cell. The oil is forced through a nozzle at high pressure to atomize it. At the same time, air is forced into the combustion chamber, where it mixes with the oil spray. The transformer delivers 10,000 V AC to the electrodes, which create a large electric arc that ignites the oil. The cad cell senses the light from the flames, and resistance drops and allows the primary control to continue operation. Should the flames extinguish, the cad cell resistance increases, and the primary control shuts off the burner motor.

WORK ORDERS

Service Ticket 5301

Customer Complaint: Expensive Heating Bills

Equipment Type: Propane Unit Heater

Precision Auto, located in rural Wisconsin, has asked their local heating contractor if there is a less expensive way for them to heat their garage. They are using

propane-fired unit heaters, which run a lot in the winter. The sales consultant suggests a waste-oil-fired furnace. The waste-oil furnace can use old motor oil, making their fuel free. In addition to saving on heating bills, they will save on used oil disposal fees.

Service Ticket 5302

Customer Request: New Construction

Equipment Type: Central Hot Water Boiler

The architect for a new high-rise being planned has asked for ideas on keeping heating costs controlled. She wants to use a large central boiler with hot water distributed throughout the building. She was considering a natural gas boiler, but the local gas company wants to put the complex on an interruptible service in exchange for favorable prices. The sales consultant suggests using a boiler fired with grade 6 fuel oil. The equipment will require a heated storage tank and the oil will have to be preheated before combustion, but the price per BTU is much lower for grade 6 fuel oil.

Service Ticket 5303

Customer Request: Furnace Replacement

Equipment Type: Oil-Fired Furnace

Dr. Greene has just purchased a house in the historic district that has an old oil-fired furnace. He wants to replace the aging, inefficient furnace with a modern, energy-efficient gas furnace. The sales consultant mentions that he does not have to switch to gas to get an efficient furnace and suggests a 95 percent efficient condensing oil furnace.

Service Ticket 5304

Customer Request: New Construction

Equipment Type: Mid-Efficiency Oil-Fired Furnace

A developer has asked a contractor for ideas for efficient heating for the homes in her subdivision in rural Canada. The developer stresses that operating efficiency is important, but so is keeping costs controlled. The sales consultant suggests a mid-efficiency oil-fired furnace as a good compromise between efficiency and cost. The consultant points out that a mid-efficiency oil-fired furnace operates about 5 percent more efficiently than a mid-efficiency gas-fired furnace.

UNIT 53—REVIEW QUESTIONS

1. List the grades of fuel oil, and give a brief description of each type.
2. What is the difference between distillate oil and a residual oil?
3. How are nozzles rated?

4. What does oil viscosity mean?
5. Which grade of fuel oil has the highest viscosity?
6. Why can oil furnaces operate at efficiencies between 80 percent and 90 percent without condensing water in the heat exchanger or vent?
7. List the available warm-air oil-fired furnace configurations.
8. Compare the efficiency of a mid-efficiency oil furnace to an older, traditional oil furnace.
9. What is the advantage of a high-pressure oil burner?
10. What are some of the challenges in building a condensing oil-fired furnace?
11. How is an oil furnace heat exchanger shaped?
12. What is the purpose of the refractory?
13. What is the typical output pressure of an oil-fired furnace oil pump?
14. What are the typical pressure settings for a pressure-reducing valve and system relief valve in a hot-water oil-fired boiler?
15. What is the purpose of an aquastat?
16. What is the difference between a direct-acting and a reverse-acting aquastat?
17. What voltage does the ignition transformer provide to the electrodes?
18. How does a cad cell sense the flames?
19. What does the primary control do?
20. What is the heating value of grade 2 fuel oil?

UNIT 54

Oil Furnace and Boiler Service

OBJECTIVES

After completing this unit, you will be able to:

1. list the operating sequence of a typical oil-fired furnace.
2. describe the procedure for purging the oil lines on an oil burner.
3. list the operating characteristics required to determine combustion efficiency.
4. explain the relationship between CO₂ flue gas percentage and combustion efficiency.
5. list the items that should be checked as part of planned maintenance on an oil burner.

54.1 INTRODUCTION

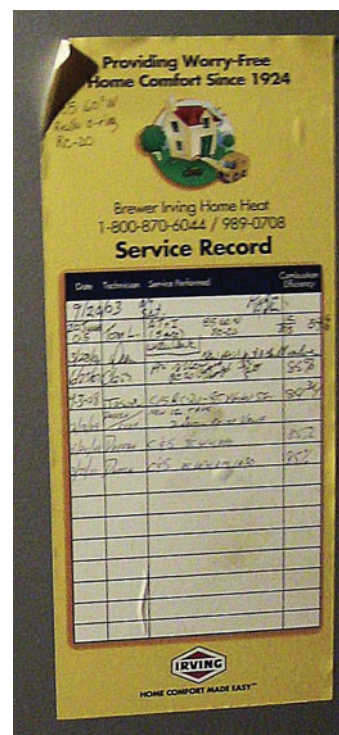

Annual service is a must for oil burners. Oil must be atomized before burning because oil is a liquid fuel. The process of atomizing the oil, mixing the combustion air with the oil, and delivering the correct amount of both oil and air has many variables that all must be correct for the process to work. Some components, such as the nozzle and oil filter, need to be changed regularly. Operating characteristics such as the oil pressure, smoke spot readings, stack temperature, and CO₂ percentage need to be checked. Failure to perform the necessary annual maintenance will result in inefficient operation and dirty combustion.

54.2 PLANNED MAINTENANCE

Good routine maintenance includes annual start-up and calibration on oil heat equipment prior to the heating season. Prior to start-up and calibration, a number of maintenance tasks should be completed, such as checking air filters, oiling motors, replacing oil filters, cleaning strainers, checking electrodes, and cleaning the cad cell. The furnace combustion chamber should be cleaned as well as the vent pipe. After the routine cleaning and replacement of components is completed, the furnace should be tested and verified during normal operation to determine that the operating and safety controls are working as designed.

Initial Preparation for Annual Tune-up

Speak with the customer to find out where the furnace is located and the best way to gain access. If the furnace is located in the basement, there may be an outside entry so you do not have to keep going back and forth through the living spaces. This way you are less likely to track dirt and soot through the house. Ask if there have been any operational problems with the furnace. Also check to see if a service record has been attached to the furnace listing the dates of previous service visits and what was done

checking the operation of the burner and controls, this also provides time for the heat exchanger surfaces to dry out. This is important if the furnace has been out of operation for a period of time. A draft drop test can be performed at this time by testing at the breech and over the fire. If the drop is greater than $-.04$ in, there is probably a buildup of soot and scale on the heat exchanger surfaces. After the furnace has run for about 5 minutes and your draft drop test is completed, it can be shut off at the emergency switch. This will test the emergency switch and also secures the power to the furnace so that you can continue with the service.

Oil Tank Filter

This is a good time to inspect the oil tank and change oil filters, as the furnace is cooling down. Many residential tanks are made of steel and will rust out over time due to the water that tends to collect in the bottom of the tank. The tank may appear to be in good condition on the outside but may be rusting from the inside out. The tank filter is connected at the bottom of the tank by a pipe nipple. Look for any signs of oil leakage in this area.

Before replacing the filter, make sure the thermal safety shutoff valve is completely closed (Figure 54-2a-c). A drip pan should be placed under the filter housing to collect any oil that spills when the dirty cartridge is removed (Figure 54-3a). Loosen the vent located on top of the filter housing to make sure that there is no oil pressure, and catch any oil that comes out in the drip pan. The main bolt that holds the filter housing in place can now be removed to access the dirty cartridge. Check for excessive water in the filter housing (Figure 54-3b).

Place the dirty cartridge into a plastic bag. Do not drain any remaining oil back into the tank, as it will be very dirty. Wipe out the filter housing with a rag and then install the new cartridge and all new gaskets and tighten the filter housing (Figure 54-4). Open the shutoff valve at the inlet of the filter housing and check for any leaks.

SAFETY TIP

Thermal safety shutoff valves have a fusible handle that melts at 165°F . In the event of a fire, the valve will automatically close once this temperature is reached.

Oil Pump Inlet Strainer

Even though there is a filter located on the outlet of the oil tank, the oil pump inlet strainer should also be replaced. This can affect the suction produced by the fuel pump which is measured in inches of mercury vacuum (in Hg). Checking the oil pump operation is further described in Unit 55.

The inlet strainer is located in the oil pump housing (Figure 54-5). Place the drip pan under the oil pump as you remove the strainer to catch any oil that will drain from it. Close the thermal safety shutoff valve located at the pump inlet. Remove the oil pump cover and its

Figure 54-2 (a) The oil tank filter is connected by a pipe nipple to the bottom of the tank; (b) Thermal shutoff valve is open; (c) thermal shutoff valve is closed.

(a)

(b)

Figure 54-3 (a) Place a drip pan under the filter housing; (b) dirty filter cartridge and housing.

gasket to access the strainer. After the inlet strainer and gasket have been replaced and the cover fastened securely, open the safety shutoff valve and check for leaks.

Purging Air from the Oil Line

On the single-pipe system, it is necessary to purge the air from the oil filter, fuel line, and fuel pump. Connect a pressure gauge on the oil line leading from the pump to the nozzle (Figure 54-6). Open the bleed connection located on the bottom of the pump housing using a small wrench (Figure 54-7). It is only necessary to open this valve until the air in the system starts to flow out. Usually, this is one half to one full counterclockwise turn of the valve. Make sure the drip pan is in place to catch the oil. When the burner is turned on, oil will flow from the bleed connection. Allow the oil pump to run until all the air is bled from the suction line.

(a)

(b)

Figure 54-4 (a) Replacement cartridge and gaskets; (b) filter housing after cleaning.

SERVICE TIP

Use this tip during purging. Place a clear plastic hose on the air purge valve and put the other end of the hose in a container. Run the pump until the hose is full of oil with no air bubbles.

A two-pipe system has both a supply line to the burner and a return line back to the fuel oil tank. Because of this, a two-pipe system is self-purging. The pump will force the air down the oil-return line and back into the tank. Even so, it is good practice when bleeding a two-pipe system to have your pump gauge connected. This will ensure that no uncontrolled oil will spray into the combustion chamber.

After the line is bled, operate the burner until the pump pressure holds steady on the gauge and then turn the pump

(a)

(b)

Figure 54-5 (a) Removing oil pump inlet strainer; (b) oil pump inlet strainer.

Figure 54-6 Oil pump connections and parts identified.

Figure 54-7 Use a small wrench to open the oil pump bleed valve.

adjustment screw. The pressure readings should change smoothly and not fluctuate up and down.

Nozzle and Electrodes

The nozzle assembly should be removed and inspected and the nozzle replaced. The electrodes' porcelain insulators should be checked for cracks, and any oil or carbon should be cleaned off (Figure 54-8). Check the setting for the electrodes. Generally speaking, they should be $\frac{3}{8}$ in apart, slightly ahead of the nozzle, and set at an angle specified by the burner manufacturer (Figure 54-9). Many

(a)

(b)

Figure 54-8 (a) The nozzle needs to be replaced and the igniters cleaned and readjusted; (b) replacement nozzle assembly.

Figure 54-9 Oil burner electrode spacing dimensions. (Courtesy of the R.W. Beckett Corporation)

manufacturers have plastic gauges that fit over the nozzle to assist in setting the electrodes.

SERVICE TIP

Replacing the nozzle as part of your routine maintenance is important because over a season the nozzle bore will be worn slightly larger as the result of oil flow. As this wear occurs, the burner efficiency is affected. Replacing the nozzle each season ensures that the burner will operate properly.

Ignition Transformer and Cad Cell

Check the springs and contacts that transfer voltage from the transformer to the electrodes and clean the cad cell eye and wires (Figure 54-10). Test the ignition transformer (Figure 54-11) for the correct voltage output to the electrodes. This is done with a special high-voltage probe (Figure 54-12). The probe reduces the voltage by a factor of 1,000; 10,000 V will show 10 V on the meter. A Donogan transformer tester or a Mitco ignitor tester (Figure 54-13) is also often used. Alternatively, a resistance test with a multimeter can be performed to measure the transformer's resistance.

Figure 54-10 Ignition transformer with cad cell located directly between the springs.

Figure 54-11 Ignition transformer.

Figure 54-12 High-voltage probe.

Figure 54-13 Mitco ignitor tester. (Courtesy of Sid Harvey's Inc.)

Figure 54-14 Flue pipe should be removed and cleaned as necessary.

SAFETY TIP

The output of the ignition transformer cannot be tested with a standard set of leads. A high-voltage probe is required. Attempting to test the ignition transformer output with regular multimeter leads will destroy your meter and possibly injure you.

Blower Wheel and Motor

Clean the blower wheel, making sure it is tight on the motor shaft. Pay attention to the air-intake slots on the air-adjustment shutter and clean if required. Check the motor shaft endplay. While in the blower compartment, check the oil pump coupling for alignment and tightness on the motor shaft to make sure it is not worn or stripped.

Flue Pipe and Draft Regulator

The flue pipe should be removed and cleaned (Figure 54-14). Check the barometric damper that is usually installed in the horizontal vent pipe between the furnace and the chimney. Make sure it swings freely (Figure 54-15). The damper has a movable weight so that it can be set to counterbalance the suction and to maintain reasonably constant flue operation (Figure 54-16). It is adjusted while the furnace is in operation and the chimney is hot.

The clean-out at the base of the chimney should not be neglected, because this can fill up with deposits over time (Figure 54-17). Once the clean-out is cleared, the chimney lining can be inspected. Place a mirror in the opening and

Figure 54-15 Make sure barometric damper swings freely.

Figure 54-16 Damper adjustment counterweight.

there should be a clearly visible passage extending all the way to the top with no broken sections of lining or brick extending into the interior of the chimney.

For furnaces with power venting, the fan blower wheel and motor should be checked (Figure 54-18) and the outside hood should be checked and cleaned.

Figure 54-17 Clean-out at base of chimney.

(a)

Figure 54-18 Power vent.

(b)

Figure 54-19 (a) Hinges on furnace front allow it to be opened; (b) clean out door swings open.

Combustion Area and Heat Exchanger

The furnace front is mounted on hinges that allow it to swing open (Figure 54-19a) or there may be a clean out door (Figure 54-19b). Electrical connections may need to be disconnected to swing the front in the fully open position (Figure 54-20). There is a braided gasket around the entire perimeter of the furnace front where it seals against the furnace (Figure 54-21). If the gasket is torn or damaged, it must be replaced. To replace the gasket, the groove that it sits in must be cleaned. A high-temperature furnace sealant can be applied to the groove to help hold the new gasket in place.

Figure 54-20 Disconnect wires to swing furnace front open fully.

Figure 54-21 (a) Braided gasket seals around the furnace front; (b) inspect the burner opening on the furnace front.

Once the furnace front is opened, the combustion chamber can be inspected and cleaned (Figure 54-22). A small vacuum cleaner may be used, but be very careful not to damage the refractory. Some of the metal surfaces will need to be lightly scraped to remove scale buildup. The combustion chamber will never look like new, but it should be cleaned enough so that no loose scale or soot remains (Figure 54-23).

TECH TIP

Carbon or soot sublimates at a temperature slightly above 800°F. Subliming is the process of changing from a solid to a vapor without becoming a liquid. This means that the area of refractory material that is carbon free was at a temperature slightly above 800°F. The line where the carbon first begins to show is the beginning of the area that was below 800°F during system operation. If you observe a furnace firebox that has far less carbon-free refractory material, this may be an indication of a low flame temperature.

The heat exchanger will need to be accessed through a cover in the top of the furnace. This cover will also have a gasket. A long-handled wire brush is used to clean the surfaces of the heat exchanger, and the soot and scale removed can be picked up with a vacuum cleaner. Figure 54-24a shows a new heat exchanger surface and Figure 54-24b, Figure c shows a heat exchanger before and after cleaning.

TECH TIP

Soot deposited on flue surfaces acts as an insulating layer, reducing the heat transfer and lowering the efficiency. Soot can also clog flues, reduce draft and available air, and prevent proper combustion. Proper burner adjustment can minimize soot accumulation. An accumulation of 0.25 in of soot is equal to 1 in of insulation, and $\frac{1}{8}$ in of soot decreases the efficiency by around 9 percent.

Figure 54-22 Soot and scale buildup in combustion chamber.

54.3 START-UP

The initial system start-up requires more than just turning on the burner. It is important that the entire operating sequence of the furnace is understood. This allows for checks of the safety system during the initial start-up.

As an example, the furnace may not light properly if there is still air remaining in the fuel lines. The result of air in the fuel line will be different for a single-pipe system as compared to a two-pipe system. In a two-pipe system, it may take longer than the cycle time of the safety switch to purge the system, and the burner may shut down before a

Figure 54-23 Combustion chamber after cleaning.

(a)

(b)

(c)

Figure 54-24 (a) New heat exchanger surface; (b) heat exchanger that requires cleaning; (c) heat exchanger after cleaning.

flame is established. It is then necessary to allow the safety switch to cool and reset before the burner can be started again. This must be repeated until the oil lines are completely purged of air and the fire is established.

However, repeated start-up and shutdown of the burner can lead to a buildup of oil in the firebox. This oil can ignite all at once and cause a flareback, which can damage the furnace and cause personal injury to someone standing close by. If you are trying to purge air from a two-pipe system, make sure that excessive amounts of oil are not collecting in the firebox. If the air is not purged after more than a few attempts, check to see if there are other operational problems.

This is why it is important to understand the operating sequence and the wiring diagrams for the equipment you are servicing.

54.4 OIL FURNACE WIRING DIAGRAMS

The primary control is the main operating control of the furnace. It controls the oil burner motor and the ignition transformer and provides flame safety. Flames are proved

using a cad cell flame sensor that senses the light of the flame. Safety against the blower circulating vent gases is provided by a blower door switch in series with the low-voltage circuit to the thermostat. Over-temperature safety is provided by the limit. Power to the primary control passes through the limit control. If the furnace reaches the limit temperature, the limit will open to shut off the power to the primary control. This in turn will shut down the burner to prevent overheating the unit. The fan switch is in series with the blower motor to control the operation of the fan. After the burner lights and the furnace has warmed up, the fan control closes to operate the fan. Properly set, this control will close at 125–130°F to start the blower motor. The fan continues to run after the burner stops, and the fan switch opens at 95–100°F to stop the blower motor.

The fan and limit control perform the same function as on a gas furnace. The safety limit will open to stop the electrical current to the burner if the furnace temperature exceeds the limit setpoint. The fan switch is set to cycle the furnace blower on when the heat exchanger heats up to the fan switch ON setting and keeps the blower operating until the heat exchanger cools to the fan switch OFF setting. The space thermostat (24 V) feeds directly to the burner low-voltage secondary control circuit. This actuates the relay and flame-detector circuit, feeding the primary line voltage to the burner motor and ignition transformer.

SAFETY TIP

The ignition circuit on an oil-fired furnace uses approximately an 8,000–15,000 V arc to continuously ignite the oil. Accidentally touching the “live” ignition transformer contacts can result in a severe electrical shock.

Cad Cell Primary Control

The original primary oil burner control, known as a stack relay, was mounted on the vent connector pipe. The bimetallic sensing element in the sensing tube would react to a rise in flue gas temperature and cause the relay to keep the oil burner operating. The stack mounted protector relay required extra wiring, as well as time and cost for manufacturing assembly or installation. To overcome this, a flame-detection relay was developed.

The cad cell is mounted directly in the oil burner housing and sees the light of the burner from the instant the flame is established. Two relays are used: 1K for control of the oil burner and ignition transformer and 2K, the sensitive relay, controlled by the cad cell. Following the circuit action in the schematic in Figure 54-25, when the thermostat calls for heat and closes the contact between T and T, current flows from the transformer through the thermostat through relay coil 1K, the safety switch (SS1), the timer contact (T2), the safety switch heater, and contact 2K1 and to the other side of the transformer. As relay coil 1K energizes, it pulls in to close contacts 1K1, 1K2, and 1K3. When 1K1 closes, it energizes the oil burner motor, oil valve (if used), and the ignition transformer. At the same time, contact 1K2 closes, which reduces the current through the safety switch heater. 1K3 is in series with the timer heater.

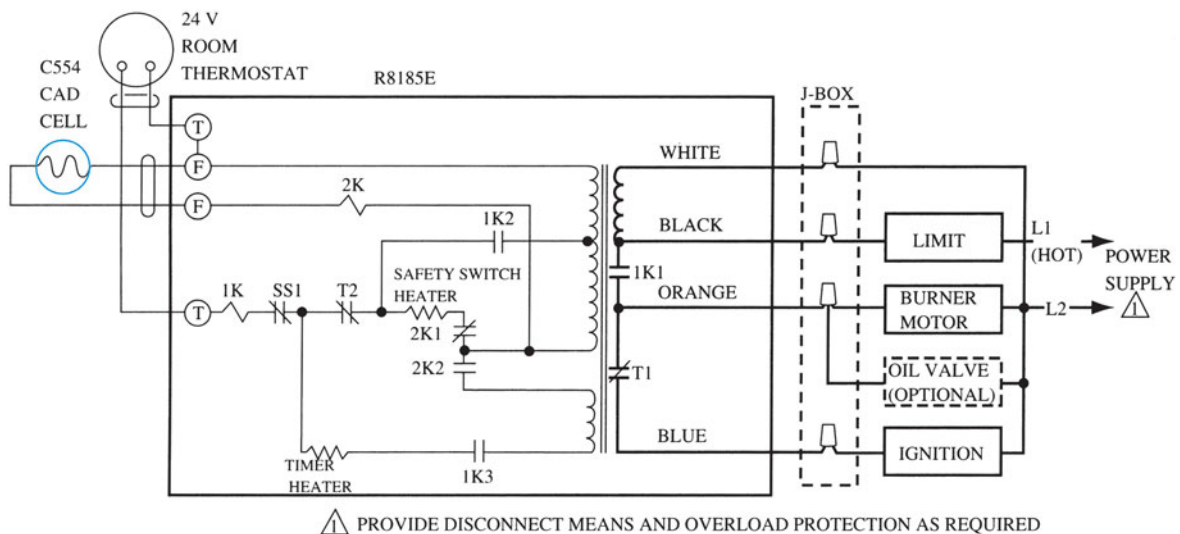

Figure 54-25 Oil burner wiring diagram, using a cad cell relay.

The safety switch heater is a type of time delay. As electrical current flows through the heater, its temperature increases to the point where it acts to open the safety switch, which de-energizes the entire circuit and shuts the burner down. This will happen if no flame is established. The delay allows enough time for the burner to light. If the burner lights, then the safety heater will be de-energized.

When a flame is established, the light strikes the cad cell and immediately reduces the resistance of the cell from over 10,000 Ω to about 1,500 Ω or less. This increases the current flow through the sensitive relay coil 2K, allowing it to pull in and close contact 2K2 and open contact 2K1, which de-energizes the safety switch heater.

The timer heater is another time delay similar to the safety switch heater in operation but not function. It thermally opens contacts T1 and T2 after a set period of time. When T1 opens, it de-energizes the ignition transformer. This allows enough time for the ignition transformer to create a spark across the burner electrodes to ignite the fuel. In this way, once enough time has passed for the burner to light, the ignition transformer is de-energized. It is only required to create an initial spark for start-up.

If flame failure should occur, the cad cell resistance will increase and current flow through the sensitive relay 2K will decrease, and the relay will drop out. This opens contact 2K2, which opens the circuit to relay 1K, and the burner shuts down.

The burner cannot come on until the timer heater has cooled sufficiently to close ignition contact T1 and relay 1K circuit contact T2. This ensures that the unit will have sufficient time to vent the furnace heat exchanger of unburned vapors as well as ensuring ignition at the next startup.

Most furnaces today still use the cad cell to sense the flame, but they now use electronic switching and circuitry rather than heaters and sensitive relays. The operating principle remains the same in that the resistance of the cad cell decreases when it detects light. These controls typically lock out after an ignition failure and must be manually reset.

54.5 OPERATING SEQUENCE

The step-by-step operating sequence is as follows:

1. The room thermostat closes to initiate a call for heat in the conditioned area.
2. If the blower door switch is closed, this causes current flow from the 40 VA transformer through the control circuits to the burner motor relay coil.
3. The relay contacts close, allowing current flow from the H, or hot, side of the supply line through the limit switch to the burner motor and ignition transformer.
4. At the same time, two other 24 V control circuits exist. One circuit is through the cad cell and the safety relay coil. The second circuit is through the safety relay normally closed contacts and the safety heater.
5. The lack of a flame causes a high resistance in the cad cell, which drops nearly all the voltage in its circuit, so the safety relay does not operate. The relay's normally closed contacts remain closed and the safety heater starts producing heat. Note that the safety heater is simply a time delay. The safety heater acts upon the safety switch contacts, which are opened by the expansion of a bimetallic element. If the burner does not light, the heater will remain on and continue to produce heat until the bimetallic element expands to the point where the safety switch contacts open and the burner motor shuts down.
6. The ignition transformer establishes a spark across the electrodes located above the nozzle. The spark at this time is only $\frac{1}{8}$ in long, the distance between the electrode tips.
7. The burner motor, which is energized at the same time as the ignition transformer, also operates the combustion air blower. It reaches full load speed within 1 second. When the full amount of air is delivered by the blower, the ignition spark is blown forward into the oil spray and the oil is ignited. This occurs directly in front of the nozzle and quickly expands into a full burst of fire in the combustion chamber.

8. The electrical resistance of the cad cell located in the fire tube decreases when the light from the fire reaches the cad cell. This decrease in resistance increases the current flow through the safety relay, allowing the safety relay to operate.
9. The normally closed contacts of the safety relay open to de-energize the safety heater and prevent the safety switch from opening.
10. The heat exchanger begins to heat up, and when the temperature reaches approximately 130°F, the fan switch contacts close and the indoor blower comes on.
11. The conditioned space temperature will begin to rise and eventually reach the setpoint of the thermostat. At this point the thermostat opens the circuit to the primary control.
12. The primary control shuts off the burner motor and ignition transformer, shutting the flame down.
13. The indoor blower continues to run until the heat exchanger cools to approximately 100°F. At this point, the fan switch contacts open and the indoor blower turns off.

SERVICE TIP

One way to test a cad cell primary control is to cover the cad cell with black electrical tape to simulate a flame failure. The control should shut down the burner the same as it would during a no-flame condition.

54.6 DELAYED-ACTION SOLENOID OIL VALVES

For oil to burn cleanly, it needs to be atomized and mixed with combustion air. Incomplete combustion will result if the oil is not delivered at the correct pressure or air is not available in sufficient quantity. Ideally, when the oil burner starts, it should reach operating speed and have the correct amount of combustion air volume before oil is supplied and combustion is established. When the burner shuts off, the oil flow and combustion should shut off instantly. Both of these are accomplished by the oil valve.

A delayed-action solenoid oil valve may be installed between the oil pump and the burner firing assembly. This type of valve, although wired to be energized at the same time as the oil burner motor (wired in parallel), has a delayed opening. This allows full operation of the burner blower and pump before oil flow is allowed. A thermistor is wired in series with the oil valve coil circuit. The thermistor has a high resistance when it is cold, limiting the current to the coil on start-up. The voltage across the thermistor causes it to heat up, and its resistance drops as its temperature rises. The thermistor's reduced resistance causes an increase in the valve coil circuit. After 8–10 seconds, the current increases sufficiently to cause the magnetic coil pull to open the valve. The valve acts the same as any other type of solenoid valve on cutoff: it closes immediately upon de-energizing the valve and motor. Thus, instant cutoff of combustion occurs.

Figure 54-26 Energy efficiency sticker.

54.7 EFFICIENCY TESTING

Checking the combustion efficiency is an important part of servicing oil-fired furnaces. Figure 54-26 shows the label on all new models listing the expected efficiency. Efficiency testing is crucial for oil furnaces because there are a number of variables that may need to be adjusted in the field. As an example, the flame efficiency increases as the refractory temperature rises. The burner is operating at peak efficiency when the surface temperature of the refractory is white hot. At this point, efficiency tests can be taken. To reach these conditions, the burner should be allowed to operate for at least 5 minutes.

The general order for taking measurements is as follows:

- Stack temperature
- Draft
- Smoke
- CO₂ or O₂
- Calculate efficiency

The make, model number, and serial number of the burner are required when referring to the manufacturer's recommendations. Check the nozzle size, type, and spray angle to ensure that the unit has been checked for proper input as well as spray angle for the shape of the refractory. Figure 54-27 shows a typical completed efficiency test sheet.

To use for future reference, a test sheet should be filled out recording the conditions to which the burner has been adjusted. The following information should be included on the test sheet.

54.8 CARBON MONOXIDE (CO)

Carbon monoxide is a colorless, odorless, tasteless poison. It is the product of incomplete combustion. Usually it is produced by too little combustion air and a smoky fire, which

Figure 54-28 High-temperature stack thermometer.

is an indication of unburned fuel. Sometimes too much air can also lead to increased levels of CO. Therefore, always operate a furnace at peak efficiency with good combustion. This will result in very low levels of CO. Normal levels within a house would be about 1 to 9 ppm. Levels above 10 ppm necessitate action being taken to bring the CO levels down. At levels above 36 ppm, the occupants should go outside to fresh air and the space ventilated. Levels above 400 ppm can lead to death.

54.9 STACK TEMPERATURE

A high-temperature thermometer, such as that shown in Figure 54-28, is inserted through a small 3/8-in hole that has been drilled through the flue pipe at the furnace outlet (Figure 54-29). The temperature of the flue products will also help to determine the efficiency of the heating unit.

DRILLED HOLE
IN FLUE PIPE
FOR TAKING
STACK DRAFT
MEASUREMENT

Figure 54-29 Drilled hole in the flue pipe to measure stack temperature and stack draft.

The cleaner the heat exchanger, the more efficiently it removes heat from the flue products as they pass through. If the CO₂ content is correct but the stack temperature is too high, this is usually a sign of excessive carbon deposit on the heat exchanger surfaces. To determine the net stack temperature, subtract the temperature of the air entering the burner from the stack temperature.

Stack temperatures for 60 to 79 percent efficient furnaces range from 400°F to 600°F. Furnaces with 80+ efficiencies have lower stack temperatures that range from 330°F to 450°F. High efficiency 90+ furnaces have the lowest stack temperatures—less than 125°F.

54.10 FURNACE DRAFT MEASUREMENTS

Draft is created by the pressure difference between the top and bottom of the chimney. This is affected by the temperature of the exhaust gases, the temperature of the outside air, barometric pressure, and humidity. A negative pressure creates more suction to pull in air, and therefore the lower the pressure, the higher the draft. If the draft is too low, then less air is drawn into the burner and the fire can become smoky. If the draft is too high, then too much air is drawn into the burner and the furnace efficiency will drop.

Draft is measured in inches of water column (in wc) because the pressure is too small for a regular pressure gauge to measure. When reading draft measurements, it must be understood that a more negative reading indicates a higher draft. As an example, a draft of -0.5 in wc would be a higher draft than -0.02 in wc.

Over-Fire Draft

For this measurement, a draft gauge is required, such as those pictured in Figure 54-30 and Figure 54-31. Insert the test pipe for the gauge through the $\frac{1}{4}$ -in hole in the observation port over the burner until the end of the pipe is beyond the inner edge of the combustion chamber. The inspection port often has a threaded bolt that can be removed for insertion of the probe pipe (Figure 54-32). To accomplish this, it is sometimes necessary to substitute a longer piece of $\frac{1}{4}$ -in copper tubing for the gauge probe pipe.

A negative pressure must be maintained on the heat exchanger to prevent the products of combustion from being forced into the occupied area. Not only do they carry free carbon or soot, but they also contain a high percentage

Figure 54-31 Stack draft gauge.

of CO. This is especially true at start-up. An over-fire draft of -0.01 to -0.02 in wc is usually required for proper operation.

CAUTION

A carbon monoxide (CO) detector is a good recommendation for the homeowner to purchase and install near any combustion equipment, whether it is gas or oil. Carbon monoxide is often referred to as the silent killer because it can go unnoticed in a home for a long period of time if the home is not protected with a carbon monoxide monitor.

Figure 54-30 Electronic combustion analyzer.

Figure 54-32 Remove threaded bolt in center of inspection port cover to insert probe.

If the over-fire draft is higher than the manufacturer's specifications (generally above $-.02$ in wc), the draft can be adjusted using the weight on the barometric damper. The draft will be decreased when the barometric damper opens. This is because the cool air mixes with the stack gases to reduce their temperature. Since cooler air rises slower than hotter air, the draft is reduced. When the draft drops below the damper setting, the counterweight closes the damper.

Some units can operate with a positive pressure of over fire, and it is important to be able to identify this type and make adjustments according to the manufacturer's specifications.

Stack Draft

The draft in the furnace stack will be higher than the over-fire draft. This measurement should be taken through the same opening in the flue pipe where the stack temperature was taken. The reading should be in the range of $-.03$ to $-.06$ in wc when the over-fire draft is $-.01$ to $-.02$ in wc.

Some manufacturers specify stack draft for a setting. This means that the flow resistance of the heat exchanger must be taken into account for burner operation. By measuring both the over-fire draft and stack draft on the new unit, the design draft resistance can be determined. To produce a negative pressure of a given amount over the fire, the stack draft must be a greater negative amount. The difference between the over-fire draft and the stack draft will be the heat exchanger draft flow resistance. For example, if it is necessary to have a stack draft of $-.07$ in wc to produce an over-fire draft of $-.02$ in wc, the heat exchanger resistance would be 0.05 in wc. When checking the unit performance after a period of operation, if the heat exchanger flow resistance has increased, then it is necessary to clean the soot from the heat exchanger flue passages.

54.11 SMOKE TESTING

A smoke tester, such as the one shown in Figure 54-33, uses a pump piston to draw flue gas products through a filter inserted in the head of the pump between the sample tube connection and the piston body. The sample tube can be inserted into the same hole in the flue pipe where the draft measurement was taken. This particular instrument requires ten slow strokes of the piston to draw the required amount of flue gas products through the filter. Some technicians want to make one more stroke on the piston to be sure they get a good test. This does not make a good test; it invalidates the test. Make only the exact number of strokes with the piston pump as specified by the manufacturer.

The filtered sample is compared to numbered rings on the test card (Figure 54-34). The smoke spot should never be higher than the No. 1 ring. If higher, the burner is receiving

Figure 54-33 Smoke tester.

Figure 54-34 Comparing smoke spot to the chart.

ing insufficient air and is not burning the carbon sufficiently. This will quickly produce carbon deposits and plug heat exchanger passages. On older units, if the sample is less than the No. 1 ring, too much air is being allowed to the burner. The CO_2 content is too low, and too much heat is being forced out of the heat exchanger. This results in considerably lower efficiency and a much higher operating cost. On newer units, the smoke spot reading should be as low as possible.

SERVICE TIP

Do not let the tip of the tube touch the far side of the flue pipe, as you may pull soot off the pipe. Be sure to clean and inspect your smoke pump regularly.

SERVICE TIP

Some furnaces are located in poorly lit basement areas. It may be necessary for you to use a drop light or flashlight to determine the difference between the shades of gray of the smoke spot test rings.

54.12 CO_2 RANGES

The theoretically perfect mix of fuel and air to burn completely with no fuel or air remaining is called stoichiometric combustion. The CO_2 percentage in the flue gas will be 15.5 percent at this point. The CO_2 percentage will drop from 15.5 percent if there is not enough air or if there is air remaining. For safety reasons, the correct air adjustment

Figure 54-35 Carbon dioxide (CO₂) analyzer.

will always result in some amount of excess air. Therefore, the CO₂ percentage should be less than 15.5 percent. How much lower depends upon the burner design. In general, more efficient burners should be adjusted to produce higher CO₂ percentages than less efficient burners.

To obtain a good sample of flue gas, the CO₂ sample is taken at least 6 in upstream of the barometric draft damper and a distance twice the diameter of the flue pipe from an elbow. This will help to avoid the possibility of outside air mixing with the flue gas sample. Again, this may mean a longer sampling tube on the analyzer. Use a CO₂ analyzer such as the ones pictured in Figures 54-35 and 54-36, following the manufacturer's instructions.

Common operating CO₂ percentages for different types of burners are as follows:

- **Old-style gun burners** These burners have no special air-handling parts other than an end cone and a stabilizer. A CO₂ reading of 7 to 9 percent should be obtained unless a CO₂ reading in this range results in more than a No. 2 smoke. If so, the CO₂ reading should be reduced until the smoke test results in below a No. 2 smoke.
- **Newer-style gun burners** Burners with special air-handling parts should be set in the range of 9 to 11 percent. This should result in less than a No. 2 smoke (closer to a No. 0 smoke).
- **Flame-retention gun burners** These burners should be set in the range of 10 to 12.5 percent with a No. 0 on the smoke test results.
- **Rotary burners** These burners should be set the same as old-style gun burners.
- **Rotary wall flame burners** Higher CO₂ settings up to 13.5 percent are available with these older burners, but the maximum of a No. 2 on the smoke test is required.

Figure 54-36 Electronic CO₂ tester.

54.13 CALCULATION OF EFFICIENCY

Three pieces of information must be known to calculate the combustion efficiency:

- The ambient temperature around the furnace
- The stack temperature
- The CO₂ or O₂ percentage of the flue gas

The ambient temperature is subtracted from the stack temperature to get the net stack temperature. This is the temperature that is added by the combustion process. Either CO₂ or O₂ percentage may be used; it is just necessary to have the correct slide rule. It is also important that the card in the slide rule be for the type of fuel being used, in this case, oil. Figure 54-37 shows a typical combustion efficiency calculator. The horizontal slider is set to the net stack temperature. Since the calculator only displays net stack temperatures every 50°F, the horizontal slide should be lined up to the temperature nearest the actual temperature. The vertical slider is then adjusted so that the tip of the arrow is at the CO₂ percentage determined by the analyzer test. The efficiency of the unit is then shown in the arrow in the vertical slider.

Figure 54-37 Efficiency calculator.

An example will illustrate how this works. An oil furnace is operating with the following characteristics:

- Stack temperature of 500°F
- Ambient temperature of 55°F
- CO₂ of 10 percent

First calculate the net stack temperature: 500°F – 55°F = 445°F

Line up the vertical window in the horizontal slide under 450°F (Figure 54-38) (this is the calculator's closest value to 445°F).

Line up the vertical slider so that the arrow points to 10 percent (Figure 54-39).

Read the efficiency in the window next to the arrow as 80.5 percent.

Figure 54-38 Efficiency calculator lined up on 450°F.

correct CO₂ range in the flue gas. The money spent on keeping the system operating correctly will be repaid in lower operating costs and longer equipment life.

WORK ORDERS

Service Ticket 5401

Customer Request: New Furnace Start-up

Equipment Type: Oil Furnace Using a Two-Pipe Fuel Delivery System

Furnace Is Above the Oil Tank

A technician attempts to purge a new two-pipe system by operating the system. After pushing the reset button twice, the technician inspects the combustion chamber for oil and finds none. Next, the technician installs a vacuum gauge on the suction side of the oil pump. With the pump running, the vacuum is only about 1 in Hg. The technician inspects the line for leaks and finds that the suction line connection is loose at the tank. The connection is tightened and the vacuum rechecked. This time the vacuum reads 10 in Hg. After pushing the reset button once, the furnace operates and fires briefly, but it goes out again. Before pushing the reset button a second time, the technician must check the combustion chamber for a buildup of oil. The inspection port is opened and the combustion chamber is inspected. Since there is no buildup of oil, the technician pushes the reset button a second time and allows the furnace to start one more time. This time, after the furnace fires, it stays going.

Service Ticket 5402

Customer Request: Annual Maintenance of Equipment

Equipment Type: Oil-Fired Furnace with a Flame-Retention Burner

A technician is called to perform an annual maintenance service on a flame-retention burner. During the efficiency testing portion of the maintenance, the CO₂ reading is 9 percent and the smoke spot reading is 0. The technician remembers that while 9 percent is fine for an older-style burner, it is too low for a flame-retention burner. Leaving it this way would result in inefficient operation. After reducing the combustion air, the CO₂ increases to 12 percent and the smoke spot remains 0.

Service Ticket 5403

Customer Complaint: High Operating Cost

Equipment Type: Oil Furnace with Older-Style Cast Iron Burner

A technician is asked to look at an older furnace whose owner is complaining about the operating cost. The technician operates the furnace and takes CO₂ percentage, stack temperature, over-fire draft, and stack draft measurements. The combustion efficiency

seems appropriate for a furnace its age, but the over-fire draft is low, only $-.01$ in wc, while the stack draft is fine at $-.04$ in wc. The technician pulls the burner out and inspects the heat exchanger. The heat exchanger is covered with a thin layer of fine soot. The technician explains to the homeowner that the soot is acting like insulation, reducing the efficiency of the furnace by keeping the heat from transferring to the air flowing over the heat exchanger. After cleaning the heat exchanger, the over-fire draft improves to $-.02$ in wc.

Service Ticket 5404

Customer Complaint: High Operating Cost

Equipment Type: Oil Furnace with Newer-Style Gun Burner

A technician is called to check a furnace that is operating inefficiently. The customer says that a previous technician had done an annual maintenance service on the burner but left no paperwork. The furnace is operating with a low smoke spot of 0 to 1, but the CO₂ percentage is only 7 percent, indicating too much combustion air. The owner asks the technician about the CO₂ analyzer and remarks that the other technician did not have one. After reducing the combustion air, the CO₂ percentage increases to 10 percent and the smoke spot still reads between 0 and 1. The technician explains that it is possible to have too much combustion air, reducing efficiency.

Service Ticket 5405

Customer Complaint: Poor Heat, Smoky Vent Gases

Equipment Type: Newer Gun-Style-Burner Oil Furnace

A technician is called to do an annual maintenance on an oil-fired furnace. The customer mentions that the furnace is not heating as well as in previous years and that the vent gases are smoky. The technician inspects the heat exchanger and finds that it needs cleaning. The electrodes appear as if oil has been hitting them. The technician cleans the heat exchanger, replaces the nozzle, and cleans and adjusts the electrodes. The smoky flue gas clears up. The technician explains that the oil mist should not hit anything; if it does, incomplete combustion and smoke will result. The soot created acts like insulation, reducing the furnace efficiency even more. Changing the nozzle ensures a good spray angle and proper atomization, while adjusting the electrodes ensures that the oil will not hit them.

Service Ticket 5406

Customer Request: Replacement Unit Start-up

Equipment Type: Flame-Retention Burner

A new technician was sent to perform a system start-up on a new oil furnace that has just been installed to replace an older furnace. While taking over-fire draft

readings, the technician notices that the readings are lower than the manufacturer's recommendations and that the barometric damper is staying wide open most of the time. After adjusting the weight on the barometric damper so that it stays shut more, the over-fire draft increases to the manufacturer's recommended $-.02$ in wc draft.

UNIT 54—REVIEW QUESTIONS

1. How does the refractory temperature affect the combustion efficiency?
2. What are normal on and off temperature ranges for the settings on the fan control?
3. Describe the procedure for purging a single-pipe gravity feed system.
4. Describe the procedure for purging a two-pipe system.
5. What pieces of information are necessary to determine combustion efficiency?
6. What can cause the heat exchanger flow resistance to increase after several years of operation?
7. Why must a negative pressure be maintained on the heat exchanger?
8. How is the door switch wired into the system in Figure 54-25?
9. What opens the contact on the safety switch in Figure 54-25?
10. Why does soot accumulation on the inside of the heat exchanger reduce system efficiency?
11. How does the cad cell operate to secure the burner in the event of a flameout?
12. What smoke spot number represents correct combustion?
13. How is net stack temperature calculated?
14. Discuss the relationship between the over-fire draft and the stack draft.
15. What is the CO_2 percentage for a perfect stoichiometric mix of oil and air?
16. Why do we not try to adjust the CO_2 percentage to the perfect stoichiometric percentage?
17. Why does excess combustion air reduce combustion efficiency?
18. How should the output of an oil furnace ignition transformer be tested?
19. What components on an oil furnace should be changed annually?
20. What angle nozzle is usually used with a round combustion chamber?

UNIT 55

Residential Oil Heating Installation

OBJECTIVES

After completing this unit, you will be able to:

1. calculate the minimum required combustion air openings.
2. discuss common applications for different oil furnace configurations.
3. discuss oil tank installation.
4. discuss factors in oil piping.
5. calculate the equivalent length of a chimney connector.

55.1 INTRODUCTION

Oil-fired furnaces provide clean, reliable heat when properly sized and configured for the application. However, they will not be clean and efficient unless they are installed correctly and maintained regularly. Proper planning for the installation is very important. The furnace should meet the heating requirements of the space. It should be located in a convenient area for the customer and for the technician who will be servicing it. As an example, furnaces installed in cramped crawlspaces are difficult to access and work on. Oil tank location also has to be considered when planning where to locate the furnace as well as flue pipe placement. Oil-fired furnaces can be very heavy, so help may be required in moving the furnace on the initial day of delivery.

55.2 EQUIPMENT SELECTION

Factors to be considered when selecting an oil furnace include the following:

- Required heating capacity
- Desired efficiency
- Systems designed for both heating and cooling
- Furnace location

Heating Capacity

The required heating capacity should be determined by using a recognized load calculation method, such as outlined in the ACCA Manual J. The furnace heating capacity should be the lowest standard capacity that is at least equal to the calculated required capacity. Since furnaces are only available in a few sizes, some oversizing is acceptable. Gross oversizing should be avoided because furnaces operate most efficiently with longer running cycles than with several short on and off cycles. Note that the heating capacity is listed as the output or bonnet capacity, not the firing rate.

A range of capacities can be achieved with the same burner by changing the nozzle. Table 55-1 shows

Table 55-1 Firing Capacity with Beckett AFG-F3 Burner

Firing Rate (BTU/hr)	Firing Rate (gph)	Nozzle
70,000	0.5	0.50 gph 70-W
91,000	0.65	0.65 gph 70-W
105,000	0.75	0.75 gph 70-B
119,000	0.85	0.85 gph 70-B
140,000	1.00	1.00 gph 70-W

the capacities available with one model furnace using the same burner and changing the nozzle size. Always refer to the manufacturer's specifications when selecting different nozzle sizes.

Efficiency

Oil furnaces are now available in efficiencies as high as 95 percent AFUE. The efficiencies and capacities available may be different from one configuration to another. The efficiency can affect the installation. If a condensing-type furnace is chosen, the venting is different than for non-condensing models. Also, condensing furnaces require drains; noncondensing furnaces do not.

Systems Designed for Both Heating and Cooling

If an air conditioner is to be installed with the oil furnace, the airflow capacity of the furnace must be adequate for the size of the air conditioner. Most manufacturers have furnaces that are considered heating-only furnaces. These furnaces do not have blower motors capable of moving the higher airflow required for air conditioning. If the furnace will be used to supply the airflow for an air-conditioning system, make certain that the furnace airflow capacity meets the requirements of the air-conditioning system.

Table 55-2 Furnace Application

Configuration	Typical Application
Lowboy	Basement, particularly basements with low headroom
Upflow	Basement with good clearance; utility room or closet with duct in attic
Downflow	Utility room or closet with duct in crawlspace
Horizontal	Attic or crawlspace with duct in same space as furnace
Multiposition	Usually any of the above applications

Location

The proposed furnace location will determine the furnace configuration. If the furnace is to be installed in an attic, a lowboy would not work. Table 55-2 summarizes the available oil furnace configurations and their typical applications. Furnaces should not be installed under stairways. Oil furnaces can be heavy and are often mounted on cement blocks rather than directly on the basement floor (Figure 55-1). When installing furnaces in the attic, make certain that the structural components of the house can support the furnace. Generally speaking, the furnace return air must not be taken from the same room that the furnace is located in.

CAUTION

Many oil-fired furnaces are located in open basement areas where they are subject to having items stored on, against, or near them. Such items constitute a major fire hazard and must be removed before you light the furnace. Caution the homeowner or resident against such storage practices.

Figure 55-1 Furnace installed in basement on top of flat cement blocks.

55.3 CLEARANCE

Furnace clearances should be maintained according to the manufacturer's specifications. Cabinet temperatures and flue pipe temperatures run warmer for oil-burning equipment, so clearances from combustible material should be adjusted accordingly. One-inch clearance is common for the sides and rear of the cabinet, compared to zero clearance for many gas units. Flue pipe clearance of 9 in or more is needed for oil-fired furnaces, whereas only 6 in of clearance is needed for natural gas.

Front clearance is extremely important, as space is needed to remove the burner assembly. Remember to leave sufficient clearance around any panel that must be removed for service. This is usually at the front of the furnace. Although many codes specify a 24-in service clearance, do yourself a favor and leave at least 36 in.

Floor bases over combustible surfaces are generally increased for oil as compared to gas. For example, in horizontal oil furnaces installed in attics, the installer must pay particular attention to recommendations related to adjoining surfaces.

CODES AND STANDARDS

Clearance is an important part of the compliance and inspection procedures required by Underwriters Laboratories (UL) for securing their seal of approval. Oil furnace installations should follow the manufacturer's instructions and all state and local codes. NFPA 31, Standard for the Installation of Oil Burning Equipment, is an excellent resource and is referenced in many state codes.

55.4 COMBUSTION AIR

Oil-fired furnaces must have an ample supply of makeup air for combustion, and the methods of introducing makeup air for a gas furnace will also be adequate for oil equipment. Combustion air should be provided from the outside near the ceiling and floor. If the openings go directly outside, each opening should be at least 1 in² for every 5,000 BTU input. If the openings pass through vertical ducts, each opening should be at least 1 in² for every 4,000 BTU input. If the openings pass through horizontal ducts, each opening should be at least 1 in² for every 2,000 BTU input.

55.5 FLUE VENTING

The flue venting system will often be dictated by the building design and structure. Many homes are built with masonry chimneys that because of their weight will extend from the basement or slab, up through the roof. Lightweight prefabricated metal chimneys are often installed as acceptable alternatives. In structures where no chimney is desired, power venting and direct venting systems can be installed.

Figure 55-2 Oil furnace connected to masonry chimney approximate dimensions. (From Advanced Residential Oilburners by George Lanthier, © 2007, by permission of George Lanthier.)

Masonry Chimneys

The most common venting practice for oil furnaces is to use a metal chimney connector and a masonry chimney (Figure 55-2). The connector is the pipe running from the furnace to the chimney. It should be kept as short as possible, with as few turns as possible, and it should have a rise of at least 0.25 in per foot of run.

In basements and equipment rooms, the connector may be either single-wall metal or type L manufactured venting material. In attics and crawlspaces, it must be type L. The connector should not pass through any floor, ceiling, or combustible walls, and the entire length of the connector should be accessible for inspection and replacement. Masonry chimneys used for oil-fired furnaces should be constructed as specified in the National Building Code of the National Board of Fire Underwriters.

The chimney should be sized according to NFPA 211 and all local codes. The cross-sectional area of the chimney should not be less than the cross-sectional area of the connector. If a metal chimney liner is used, it should comply

Table 55-3 Minimum Gauge for Single-Wall Chimney Connector

Connector Diameter	Minimum Gauge
Less than 6 in	26
6–10 in	24

with UL 64. Oil furnaces should not be common vented with wood-burning appliances, fireplaces, or gas-burning appliances. They may be common vented with other oil-fired appliances. If more than one oil-fired appliance is vented into the same chimney, the cross-sectional area of the chimney must be at least equal to the combined cross-sectional areas of the connectors.

Masonry chimney connector size If a single-wall connector is used, the metal needs to be a much heavier gauge than the galvanized metal normally used for ductwork. Table 55-3 shows the minimum gauge for different connector sizes.

The connector must not be smaller in cross-sectional area than the flue collar on the furnace. The chimney connector should have a total equivalent length of no more than 75 percent of the chimney height. The total equivalent length is based on the actual length of the connector plus the equivalent length of any fittings. Table 55-4 shows the equivalent lengths for several common fittings.

The chimney height is based on the height measured from where the connector enters the chimney. For example, a 6-in connector that is 8 ft in actual length with two 90° ells has a total equivalent length of $8 + 11 + 11 = 30$ ft. This must be no more than 75 percent of the chimney height above where the connector enters. Thus the chimney above the connector entrance must be $30 \div 0.75 = 40$ ft.

Unfortunately, this is higher than many residential chimneys. Replacing the 90° ells with 45° ells reduces the total equivalent length to $8 + 5 + 5 = 18$ ft. By using the 45° ells, the chimney height above the connector entrance need only be $18 \div 0.75 = 24$ ft.

Prefabricated Metal Chimneys

Prefabricated lightweight metal chimneys are rated for all flues, Class A and Class B. Class A flues are used for solid and liquid fuels, while Class B flues are made specifically for gas-fired equipment. Oil furnaces may also be vented using Type L vent, which is specifically made for oil furnaces.

The entire vent system can be constructed of type L venting material, providing the furnace manufacturer approves

Table 55-4 Connector Fitting Equivalent Length in Feet

Fitting	3 in	4 in	5 in	6 in	7 in	8 in	9 in	10 in
Tee	19 ft	25 ft	31 ft	38 ft	44 ft	50 ft	56 ft	63 ft
Wye	10 ft	13 ft	16 ft	20 ft	23 ft	26 ft	29 ft	32 ft
90° ell	5 ft	7 ft	9 ft	11 ft	12 ft	14 ft	16 ft	18 ft
45° ell	3 ft	4 ft	4 ft	5 ft	6 ft	7 ft	8 ft	9 ft

L-Vent Used as a Complete Interior Venting System

3" clearance to combustibles make L-Vent a space saving interior application.

Figure 55-3 Type L vent (Courtesy of Selkirk Corp.)

the furnace for use with type L venting systems. Type L venting material should not be used with appliances with vent gas temperatures exceeding 550°F. Figure 55-3 shows a type L venting system for connection to an oil-fired furnace.

The roof dimension of the vent or chimney is the same for both gas and oil. Since oil-fired furnaces operate on positive pressure from the burner blower, it is important to have a chimney that will develop a minimum draft of $-.01$ to $-.02$ in wc as measured at the burner flame-inspection port. However, there are some newer residential units that can be designed to operate with a positive over-fire draft.

Power Venting

The advantage of power venting is that no chimney is required, but it can cause noise and vibration in the building. Power venting systems are designed with a blower located in the flue pipe either outdoors or indoors just before the outside wall (Figure 55-4). Power venting systems require that the furnace primary control allows for a delayed burner firing at start-up. This allows the vent blower to come on and produce a draft before the burner firing sequence begins. The blower must also continue to run for a period of time after the burner shuts down to ensure venting of all the combustion gases.

Figure 55-4 Power venting.

Direct Venting

Similar to power venting, direct venting systems require no chimney. However, direct vent systems do not use a blower but instead rely on the power of the burner fan to push the combustion gases out of the building. They also use a sealed combustion chamber with air brought in from the outside. A disadvantage to this type of system is that the pressure inside the furnace vent is higher than the pressure in the building. Because of this, the vent system needs to be properly sealed to prevent leakage of combustion gases into the building.

Barometric Damper

Standard efficiency oil furnaces require a barometric damper, in the chimney connector. Some sealed combustion furnaces do not use a barometric damper. Condensing furnaces also do not use a barometric damper.

The barometric damper should be installed in the chimney connector as close to the furnace as possible and at least 18 in away from any combustible wall or ceiling. Older units may have a stack safety switch, and if that is the case, the barometric damper should be at least 18 in downstream from the stack switch, as in Figure 55-5.

The barometric damper should not be installed on the end of a bull-headed tee but on the branch of a tee that is in line with the connector. Make sure the damper is oriented the way it was designed. A damper that is designed to be installed with the pivots horizontal to the ground will not work if it is installed on its side (Figure 55-6). The draft in the connector will need to be measured and the barometric damper adjusted during the initial start-up.

55.6 SYSTEM WIRING

The vast majority of oil furnaces and boilers operate on 115 V circuits. The wire conductors must be sized to carry the maximum circuit amperage of the furnace or boiler.

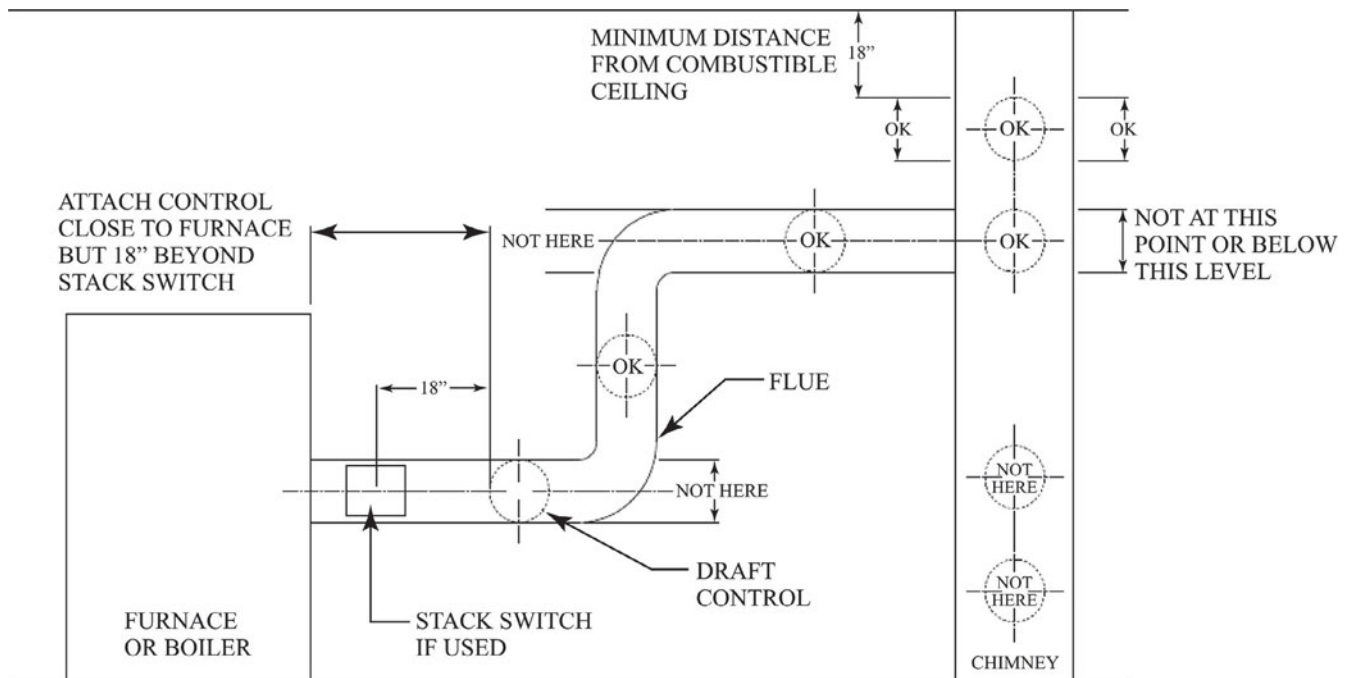

Figure 55-5 Barometric damper location. (Courtesy of Field Controls)

Figure 55-6 Barometric damper.

The manufacturer's instructions typically specify the correct wire size (Table 55-5).

Three wires are typically connected for the power wiring: a hot wire, a neutral wire, and a ground wire. The ground wire is connected to the ground lug on the equipment cabinet. It is important that the polarity of the power wiring is connected correctly. The ground is important for safety. The connections to the hot wire and neutral

must not be swapped. Some units with electronic control boards will not operate if the hot and neutral are swapped. Typically, the hot connection is black and the neutral is white.

SAFETY TIP

Many older furnaces were originally wired without a bonding safety ground to the cabinet. When replacing these furnaces, you should always run a new power wire with a hot, neutral, and ground so that the furnace can be properly grounded. Leaving the furnace cabinet ungrounded is dangerous.

Control Wiring

The control wiring for a heat-only application consists of two wires. Typically the control wires connect to the two T

Table 55-5 Wire Sizing Guide

Unit Size	Volts-Hertz-Phase	Operating Voltage Range		Max Unit Amps	Min Wire Gauge	Max Wire Length (ft) [†]	Max Fuse or Circuit Breaker Amps [‡]
		Max*	Min*				
105-12	115-60-1	132	104	12.2	14	26	15
120-20	115-60-1	132	104	15.7	14	26	20

*Permissible limits of voltage range at which unit will operate satisfactorily

[†]Length shown is as measured one way along with path between unit and service panel for maximum 2 percent voltage drop.

[‡]Time-delay fuse is recommended.

terminals on the primary control and to the R and W terminals on the thermostat.

The control wiring for both a heating and cooling application consists of five wires. Two wires are used for heat and three more for the cooling and fan operation. Typically, separate transformers are used for heating and cooling because the primary control has its own transformer.

SERVICE TIP

Most heating and cooling thermostats have connections for two 24 V inputs. These are normally labeled RH (red for heating) and RC (red for cooling). Frequently, the thermostats come with a jumper already installed between the two terminals, because most systems only have one transformer. Oil heating systems with air conditioning typically have a separate cooling transformer, so the jumper should be removed.

Wireless Thermostats

The thermostat should be located about 5 ft from the floor on an inside wall where there is good natural circulation. Running thermostat wires for a newly constructed building is generally fairly simple before the drywall is hung. It will be more difficult running thermostat wires once the interior finish work of the building is completed. Some heating systems also have multiple zones that require multiple thermostats located in different rooms or different stories of the building. This involves running additional wires.

Wireless thermostats are now available that eliminate the need for running wires to individual zones. The control unit is connected to the furnace control wiring and to the wireless transmitter. The transmitter responds to wireless signals from the individual zone thermostats, which are then fed back to the control unit. An example of a system using two zone thermostats to control damper position is shown in Figure 55-7.

TECH TIP

When the need arises to rewire a thermostat, use the old thermostat wiring to help pull the new wire through the wall. Attach the new wire securely to the old wire on one free end. Then pull slowly from the other end until the new wire comes through.

55.7 OIL STORAGE TANK TYPES

Oil storage tanks for residential furnaces typically hold anywhere from 100 to 330 gallons. The most common storage tank is typically made of steel and holds 275 gallons of fuel oil (Figure 55-8). Smaller tanks are used for mobile homes or in locations where a larger tank cannot be easily installed. Some tanks are coated on the outside with polyethylene to reduce external corrosion. Double-wall tanks are designed

(a)

(b)

Figure 55-7 (a) Two-zone wireless thermostat system; (b) wireless transmitter.

Figure 55-8 Metal 275-gallon oil storage tank.

(a)

(b)

Figure 55-9 Double-wall oil storage tank.

to prevent spillage if the inner tank leaks. These can be made of fiberglass, while others have an inner tank made of polyethylene with an outer steel tank surrounding it. A double-walled 275-gallon capacity with an inner nonmetallic tank and a galvanized steel exterior is shown in Figure 55-9.

The tank should be sized properly for the customer. Undersized tanks will need to be filled too frequently. Oversized tanks are subject to excessive condensation and poor fuel quality due to long storage periods. A properly sized tank should supply about one-third of the expected annual fuel consumption. As an example, a 275-gallon tank filled three times a year would be an appropriate size for an annual consumption of 825 gallons.

Residential fuel oil storage tanks are nonpressurized and vented to the air. There are two pipes connected to the top of the oil storage tank. One pipe is used for filling the tank with oil, and the other pipe is a vent. Figure 55-10 shows the typical arrangement of these pipes outside the residence. As the oil fills the tank, air leaves through the vent.

The fill pipe has a cap that is clearly marked, and it should contain an insect screen. The vent pipe cap is designed to whistle while the tank is being filled and air is rushing out through it (Figure 55-11). This whistling will stop

(a)

(b)

Figure 55-10 (a) Outside oil fill and vent pipes; (b) inside oil fill and vent pipes connected to the oil storage tank.

(a)

(b)

Figure 55-12 Oil storage tank level indicator.

sounding when the level of oil in the tank rises up to the full level in the tank. The tank will also have a level indicator mounted on top (Figure 55-12).

TECH TIP

When planning an oil-fired furnace installation, the placement of the oil fill line must be considered. It should be located conveniently for the oil delivery truck to access. However, do not allow the piping to pass under stairs or entries.

55.8 OIL STORAGE TANK LOCATIONS

Because of environmental concerns, many local and state governments have outlawed the installation of oil storage tanks below ground. Check the local building codes to see whether it is possible to install a tank underground. In some localities, existing underground tanks are not allowed to be replaced. Regardless of location, the installation of the fuel oil tank and connecting piping must conform to National Fire Protection Association (NFPA) standard 31 and to local code requirements.

Inside Tanks

Typically, most residential storage tanks are located inside, often in the basement (Figure 55-13). This is preferred because the oil is warmer and the tank is subject to less external corrosion. The inside temperature will be steady, leading to less condensation in the tank. Leaks will be identified quickly due to the strong odor of the fuel oil. When installed inside, the tank is required to be at least 5 ft from any flames or heat-producing equipment.

Figure 55-13 Oil storage tank located inside the basement.

Outside Tanks

These are used if the space inside is limited—for example, if there is no basement to hold the tank. This type of arrangement does not do well in very cold climates. The fuel will gel due to the low outside temperatures and plug filters and lines. Some fuel suppliers will mix a grade 1 fuel or kerosene with the normal grade 2 oil. This lighter mix of fuel will flow better during conditions of low outside temperatures. Outside tanks will have the fuel line coming from the top of the tank, and it should be insulated up to the point where it enters the building. If the oil tank is placed outdoors aboveground, firm footings must be provided (Figure 55-14).

55.9 OIL LINES

Residential furnaces normally use 1/2-in outside diameter (OD) copper oil lines connected with flared fittings. The total number of fittings should be kept at a minimum, and compression fittings are not to be used. The connection from the oil storage tank to the burner oil pump can be arranged as a one-pipe or two-pipe system. For either type, there will be a thermal safety shutoff valve and filter assembly at the tank and a thermal shutoff valve located at the inlet to the oil pump.

For an inside installation, it has been common practice to run the oil line through the concrete in the basement floor. However, the line should not be allowed to touch concrete or soil and should be shielded by flexible plastic conduit or a coated copper line. Running the oil line through the floor is done to limit the amount of suction required by the pump. This arrangement allows for the oil to flow to the pump by gravity and reduces the total vacuum required at the suction of the pump.

Figure 55-14 The outside oil storage tank is mounted on a cement slab, and the oil line is connected at the top of the tank.

It is also common practice to run the oil pipe up and across the basement floor joists and back down to the oil pump (Figure 55-15). This eliminates the trouble involved with running the oil line through the concrete floor. It is also preferred to running the oil line on top of the basement floor, where it may be easily subject to damage. In either case, the oil line must be shielded with flexible plastic conduit.

Placement of the oil line depends on the vertical lift and horizontal run of the oil line, which will affect the suction required by the oil pump. The suction produced by the fuel pump is measured in inches of mercury vacuum (in Hg). About .75 to 1 in of Hg vacuum is required for each foot of vertical lift and for every 10 ft of horizontal supply piping. The vacuum required for lifting the oil due to the combined resistance of vertical lift and piping length should never be allowed to exceed 6 in Hg with a single-stage single-pipe, 12 in Hg with a single-stage two-pipe, or 17 in Hg with a two-stage two-pipe system. If the vacuum at the pump exceeds these limits, entrained air in the oil will expand and cause capacity and noise problems. This will reduce the life of the oil pump and can also lead to unstable flame conditions.

Single-Pipe System

A single-pipe system uses one oil line from the tank to the oil pump. This is the preferred method of installation. If the tank and the oil lines are installed such that the total vertical lift and horizontal run do not exceed 6 in Hg vacuum, then a single-pipe system should be installed.

Two-Pipe System

Two-pipe systems are required when the oil tank is located below the fuel unit and a high lift and/or long run of fuel line exists. If the total vacuum required at the suction of the oil pump is greater than 6 in Hg, then a two-pipe system will need to be installed. A return line from the pump delivers oil

(a)

(b)

Figure 55-15 (a) The oil line shown runs from the tank to the floor joists and then down again to the furnace; (b) oil lines should be shielded with flexible plastic conduit.

back to the fuel tank (Figure 55-16) or to a fuel de-aerator to allow for the entrained air to be removed from the oil.

Many oil pumps are designed for both single-pipe and two-pipe systems. By placing a bypass plug in the housing, the pump can operate as a single-pipe or a two-pipe system. The plug is removed for single-pipe operation. Generally the bypass plug must be installed for two-pipe systems, but some newer pumps today do not require a bypass plug. The major disadvantage of the two-pipe system is the potential for a leak to develop in the fuel return line, which is under positive pressure. A small leak in this line could result in an extensive oil spill over the course of several days of operation.

Figure 55-16 An oil storage tank for a two-pipe system showing the supply and return lines.

55.10 OIL SAFETY VALVES

Some fuel oil systems are installed so that the oil tank is at a higher elevation than the furnace. This makes getting the fuel to the burner easier. Unfortunately, it also makes it possible for any leaks in between the tank and the pump to leak oil continuously, especially when the furnace is off. In a worst-case scenario, an entire tank of oil can leak out. The purpose of the oil safety valve is to prevent line leaks from draining the tank and causing environmental damage. Many state and local codes require oil safety valves. Refer to the latest edition of the National Fire Protection Association Standard (NFPA 31) for the installation of oil burner equipment.

If the top of the oil supply source is more than 8 ft above the fuel unit, an oil safety valve will need to be installed. The valve is normally closed and will only open if there is a vacuum on the outlet side of the valve. When the burner is off, if there is no vacuum, then the valve remains closed and oil flow is stopped. If the fuel lines are tight, a vacuum is created when the burner starts, allowing the oil to flow. However, air will be sucked into any leaks, reducing the vacuum on the line and keeping the valve closed. Since the valve remains closed, oil will not leak out. This not only prevents leaks but also encourages customers to get the leaky lines repaired because the furnace will not fire. Without the oil safety valve, small leaks can be ignored because the unit will still operate and heat.

55.11 START-UP PROCEDURES

Some preliminary checks and steps are necessary before attempting to start the furnace. With the main power supply turned off, check to see that the following are in place:

- The correct nozzle size has been selected for the desired input rate.
- All shipping supports are removed.
- Power wiring is properly connected.
- Control wiring is properly connected.
- Blower access door is secured in place.
- Valve on the oil supply line is open.
- Reset button on the primary control is pushed down.

- Flame observation door and all clean-out access covers are closed.
- The thermostat is set to HEAT at a temperature higher than the room.

After all of the above items have been checked, set the disconnect switch to OFF and energize the circuit to the furnace. Check the voltage at the disconnect switch and verify that it is the correct voltage, usually 115 V.

Operational Check

To correctly adjust the burner, it will be necessary to measure the oil pump pressure, stack temperature, and carbon dioxide flue gas percentage.

All air should be purged from the fuel lines and a pressure gauge installed on the pressure port of the oil pump. The manufacturer's literature or a data plate on the oil burner can be used to identify the correct pump pressure. The most common pressure has been 100 psig for many years, but more recent oil burners may operate at a higher pressure. Start the burner and compare the oil pump pressure to the recommended pressure and adjust it as necessary.

The operation of the barometric damper should be checked. The manufacturer's instructions should list the recommended draft pressure between the damper and the furnace; -0.02 in wc is common. Adjust the weight on the barometric damper to achieve the correct draft.

The correct flame should have no smoke, as measured by a smoke spot test. The CO_2 level should be 10–12.5 percent. If there is smoke in the flame or if the CO_2 level is outside of the 10–12.5 percent range, you need to adjust the air. To do this:

- Adjust the air-inlet vane until you see a trace of smoke in the flame.
- Measure the CO_2 content of the flue gas.
- Open the air until you have lowered the CO_2 by 1 to 2 percent.
- The correct flame should have no smoke and the CO_2 level should be 10 to 12.5 percent.

The flue gas should be checked to determine the combustion efficiency. To do this, measure the actual stack temperature and then subtract the equipment ambient temperature. The result will be the net stack temperature. The combustion efficiency can then be calculated using the CO_2 percentage, the net stack temperature, and a combustion efficiency slide rule.

Other items to check are the carbon monoxide level of the flue gas, the temperature rise, and blower current draw once the indoor blower comes on. Ideally, the flue gas should have no carbon monoxide, but trace amounts of up to 50 ppm are acceptable.

SERVICE TIP

Pushing the safety reset several times on an existing furnace is not a safe practice because oil may already be sitting in the combustion chamber and every push delivers more oil. On a new installation, the lines are full of air. A two-pipe system will purge itself, but it may take several pushes. Always check the combustion chamber for excess oil accumulation before pushing the safety reset.

UNIT 55—SUMMARY

Proper installation and start-up are required for oil-fired appliances to burn cleanly and efficiently. There are several key components to ensure a successful installation. The furnace capacity needs to match the heating load. The proper oil tank must be installed along with the correct fuel line arrangement. There must be adequate combustion air supplied to the furnace as necessary. Always refer to both the NFPA and local codes for guidance. The correct exhaust vent and vent connector need to be installed at the proper locations and at the proper heights. Power and control wiring need to comply with the manufacturer's recommendations for voltage and current demand along with wire sizing requirements. Final installation will include combustion measurements and adjustment.

WORK ORDERS

Service Ticket 5501

Customer Complaint: Unit Will Not Operate

Equipment Type: Oil-Fired Furnace with Electronic Controls

A technician answers a service call to start a newly installed oil furnace. After making the necessary pre-start checks, the technician tries to start the furnace and nothing happens. The technician investigates further and finds that there is a fault code flashing on the control board LED.

The technician refers to the installation manual that came with the furnace and finds that the flash pattern is listed as "incorrect power polarity." This leads the technician to check the power wire connections. The black power wire is connected to the white on the furnace, and the white power wire is connected to the black on the furnace. The technician swaps the wires and the furnace operates properly.

Service Ticket 5502

Customer Complaint: Unit Does Not Fire When Started

Equipment Type: Oil-Fired Furnace with Two-Pipe Fuel Supply, Tank Below Furnace

A technician is sent to start a newly installed oil-fired furnace. Initially the furnace appears to start when it receives a call for heat, but it does not fire. After 2 minutes, the primary control shuts down on safety. Since this is a new installation and the furnace has not fired, the technician assumes that the lines have not been completely purged of air.

Sometimes with a two-pipe fuel supply such as this, purging can be accomplished by restarting the furnace, thereby allowing the air to be pushed through

the supply line into the return line and back to the tank. After pushing the reset button once, the furnace operates and the fires briefly but goes out again. Before pushing the reset button a second time, the technician must check the combustion chamber for a buildup of oil. The inspection port is opened and the combustion chamber is inspected. Since there is no buildup of oil, the technician pushes the reset button a second time and allows the furnace to start one more time. This time, after the furnace fires, it stays going.

Service Ticket 5503

Customer Request: Furnace Change-out: Reconnect Vent

Equipment Type: Oil-Fired Furnace Vented into Masonry Chimney

A technician is sent to install the chimney connector to a new oil-fired furnace that has just replaced an older unit. The customer complained that the old furnace would sometimes admit smoke into the basement. The technician realized that this may have resulted from an improper vent connection.

The old furnace metal connector was single wall and the draft regulator was connected to the end of a bull-headed tee. The technician decides to run a type L chimney connector and places the draft regulator on the branch end of an in-line tee. Also, the 90° ell and tee are replaced by two 45° ells. The draft regulator is adjusted and the over-fire draft is measured to be $-.02$ in wc. The draft in the chimney connector is measured to be $-.04$ in wc. The system operates properly and there is no oil smell or smoke in the basement.

Service Ticket 5504

Customer Complaint: Unit Does Not Operate

Equipment Type: Oil-Fired Furnace with Electronic Controls

A technician has installed a new electronically controlled oil furnace to replace an aging furnace and used the same power wire configuration on the new furnace. The technician had not paid attention to the fact that the power line to the old furnace did not have an equipment ground.

After conducting the routine prestart checks, the furnace was started but nothing happened. The technician investigated further and found that the control board LED was flashing. The technician refers to the installation manual that came with the furnace and finds that the flash pattern is listed as "furnace not grounded." The technician quickly realizes what the mistake is and runs a new grounded power supply. With the unit grounded, the furnace starts and operates correctly.

Service Ticket 5505**Customer Complaint: New Hydronic System Has Cold Zone****Equipment Type: Oil-Fired Boiler with Zoned Hydronic Radiant Floor Heat**

A technician answers a service call for a recently installed hydronic heating system. The customer says that the problem is that one zone is colder than the others. This is especially true on cold days when all zones are calling for heat.

The first thing the technician checks is the zone valve, and it is opening and hot water is passing through it. However, the return pipe from that zone is 15°F cooler than the other two zones. This low return temperature indicates poor water flow to that zone. The technician fully opens the balancing valve for the cold zone and partially closes the balancing valves for the other two zones. After 30 minutes of operation, the return temperature of all zones is within 5°F. A check of the floor temperature in all three zones with an infrared thermometer shows that the floor temperatures are now around 90°F.

UNIT 55—REVIEW QUESTIONS

1. What factors should be considered when selecting an oil-fired furnace?
2. What is the proper service clearance that should be allowed when installing a furnace?
3. What is the firing rate of a furnace with a Beckett AFG-FG burner and a 0.75 gph 70-B nozzle? (Refer to Table 55-1.)
4. What is the heating capacity of an 80 percent efficient furnace with a Beckett AFG-FG burner and a 0.75 gph 70-B nozzle? (Refer to Table 55-1.)
5. What would be the required vacuum for an oil furnace located 5 ft above the oil tank with a horizontal run of 20 ft?
6. What national standard is a good reference when installing oil furnaces?
7. What free air opening would be required for an oil furnace installed in a confined space if the air was coming through horizontal ducts and the furnace had a Beckett AFG-FG burner and a 0.65 gph 70-W nozzle? (Refer to Table 55-1.)
8. Calculate the equivalent length of a 6-in-diameter chimney connector with two 45° ells and 8 ft of pipe.
9. How high must the chimney be above the connector entrance for the connector in question 8 to operate properly?
10. What type of material must be used for a chimney connector in a crawlspace?
11. Describe where the barometric damper should be installed in the chimney connector.
12. How would the primary control need to differ to accommodate power venting?
13. What is a disadvantage to direct venting an oil-fired furnace?
14. What problems can arise from an oversized oil storage tank?
15. How much fuel should a properly sized oil storage tank hold?
16. What is the function of an oil safety valve?
17. Give a prestart checklist when checking a newly installed oil furnace.
18. What measurements should be taken when setting up a new oil furnace?
19. What national publication is a good reference for chimney construction?
20. What types of appliances may oil furnaces be common vented with?

UNIT 56

Troubleshooting Oil Heating Systems

OBJECTIVES

After completing this unit, you will be able to:

1. discuss common oil delivery problems.
2. discuss common ignition system problems.
3. discuss common primary control problems.
4. explain how soot forms and what problems soot buildup can lead to.
5. describe safety precautions that should be followed when checking a system with a tripped primary control.
6. determine likely causes of oil heating system failures using a troubleshooting chart.

56.1 INTRODUCTION

Oil furnaces use a liquid fuel that must be atomized before burning, which provides for a unique set of problems when compared to gas furnaces. Operational troubles associated with oil furnaces can be related to the process of atomizing the fuel, mixing it with air, and igniting it with a high-voltage spark. Though these are typical, in some cases the problems are much simpler. A thorough understanding of how all the furnace components operate will help you to identify and troubleshoot system malfunctions.

56.2 OIL BURNER PROBLEMS

Oil burner problems can be grouped by the main components of the oil burner:

- Oil burner motor problems
- Oil pump problems
- Nozzle problems
- Ignition system problems
- Primary control problems

Oil Burner Motor Problems

The burner motor is usually a split-phase motor with a centrifugal switch and a manual-reset-type overload (Figure 56-1). Motor problems can include open, shorted, or grounded windings, a defective centrifugal switch, or even on rare occasions a defective overload. Regardless of the specific motor malady, the solution is generally motor replacement. It is usually not practical to repair motors in the field.

Symptoms that indicate problems with the burner motor include the following:

- Burner motor does not start
- Burner motor runs but trips out on overload
- Burner motor runs but does not produce enough oil pressure

Burner motor does not start If the motor will not start, begin by checking to see if the motor is receiving the correct

Figure 56-1 Oil burner motor reset button. (Courtesy of InspectAPedia.com)

voltage. If the motor has no measured voltage, then the problem is not with the motor. If the motor is receiving voltage and not operating, try pushing the manual reset for the motor overload. If the overload has tripped, the red button will be sticking out. Try pushing it to reset it. If the motor tries to start but cannot, either the motor is stuck or it is defective. Turn the power off and check to see if the motor is binding by spinning the combustion blower by hand. If it will spin easily, the motor is not bound. If the motor overload is not tripped, it is receiving voltage; if it is not bound but still will not run, then the motor is damaged. This may be traced to the windings or the centrifugal switch; however, rather than trying to repair it, the recommended remedy is to replace the motor.

If the fan will not spin, or is very difficult to turn, then the fuel pump is binding, the fan is hitting the housing, or the motor bearings are seizing. Disconnect the motor from the coupling that drives the oil pump (Figure 56-2). If the oil pump is the problem, the motor will now turn freely. If it does not turn freely, then the motor bearings are most likely the problem and the motor should be replaced. Once

Figure 56-2 (a) Oil pump drive coupling location; (b) oil pump and drive shaft.

the bearings become so dry that they seize, they cannot be fixed by lubricating them.

Burner motor runs but trips out on overload If the motor runs but trips out on overload, check the motor's operating current and compare it to the full load amperage (FLA) marked on the motor. If the overload trips without the current exceeding the rated FLA, the overload is weak and the motor needs to be replaced. If the operating current exceeds the FLA, then look for items that might be binding the motor. Disconnect the coupling to the oil pump to see if the motor will operate with the correct operating current. If the oil pump is the problem, the motor will now turn freely. If the motor bearings are the problem, the motor should be replaced.

Burner motor runs but does not produce enough oil pressure If the motor runs but the oil pressure is low, check the coupling that drives the oil pump. If the coupling is cracked or stripped out, the motor will run but the oil pump will turn slowly, or not at all. Replacing the coupling will correct this.

Oil Pump Problems

Oil pump problems include the following:

- Seized oil pump
- Oil pump pressure not correct
- Bypass plug incorrectly applied
- Leaky shutoff

Seized oil pump If the oil pump will not turn, it is seized and should be replaced. If this is the case, then the quality of the oil should be checked. Water and sludge in the pump can cause it to seize. Cleaning the oil tank to remove accumulated debris and sludge is a good precautionary measure whenever an oil pump is replaced.

Oil pump pressure not correct Check the inlet strainer screen if the pump will not maintain the correct pressure (Figure 56-3). If the system is a two-pipe system, check to see that the bypass plug is installed. If the system is a one-pipe system, check to see that the bypass plug has been removed. If the screen is clear and the pressure is still too low, try adjusting the pump's output pressure. Turn the adjustment screw clockwise to increase the pressure.

A leak in the suction line can also cause poor oil pressure by letting air in. Disconnect the nozzle line connector and direct its output to a container. Run the burner and observe the oil stream. The stream should be clear and steady. If air is being drawn in through a leak in the suction, the oil stream will be frothy or bubbly. Finding and repairing the leak is necessary before proceeding. If none of the troubleshooting methods result in proper operation, then the pump is damaged and should be replaced.

Bypass plug incorrectly applied The oil pump delivers more oil than the burner can use. The extra oil must either

Figure 56-3 Oil pump inlet screen.

be bypassed internally in the pump or sent back to the tank through a separate oil-return line. By placing a bypass plug in the housing, the pump can operate as a single-pipe or a two-pipe system. The plug is removed for single-pipe operation. Single-pipe operation is used where the oil tank is above the burner, and gravity oil feed to the burner is permitted. Generally the bypass plug must be installed for two-pipe operation. However, some newer pumps today do not require a bypass plug. Two-pipe operation is needed when the oil tank is located below the fuel unit and a high lift and/or long run of fuel line exists.

Leaky shutoff When the burner motor stops, the oil pump should shut off tightly to prevent continued oil delivery into the combustion chamber. If the pump cutoff is working properly, the output pressure should not drop past 80 psig or not more than 20 percent below the operating pressure. If the pressure drops below these levels, the cutoff is leaking and the pump should be replaced.

Nozzle Problems

The oil mist from the atomized spray cone should not come into contact with any part of the combustion chamber. If it does, the oil will not burn completely, and sooty, inefficient combustion will result. Nozzles become worn over time, and the atomization becomes less complete, resulting in incomplete combustion. The nozzle filter can become clogged over time and produce a poor spray pattern. Poor combustion that persists and cannot be adjusted can be a sign of a worn or dirty nozzle. Typically, the nozzle should be changed every year to ensure correct operation.

Ignition System Problems

Ignition problems can result in delayed ignition or no ignition. Ignition components include the ignition transformer, the electrodes, and the contacts that transfer electricity from the transformer to the electrodes. The transformer delivers 10,000 V AC to the electrodes, producing an arc between them.

This high voltage arc can be diminished by the following:

- Low transformer primary voltage
- Improper electrode gap
- Cracked or dirty porcelain insulators on the electrodes
- Poor contact between the electrodes and the transformer
- A weak transformer

If the oil burner has been delivering oil and it has not been igniting, the first thing that needs to be done is to clean the excess oil out of the combustion chamber. Turn off the power and disconnect the control wires so that the burner will not try to light. Some furnaces have a clean-out port that can be used to gain access to the combustion chamber. If the furnace does not, it will be necessary to remove the burner assembly to allow for access. Carefully clean out any accumulated oil, but be careful not to damage the refractory.

When the furnace starts, the ignition spark should make a buzzing sound. If you do not hear the arc, check the transformer primary voltage. If the transformer is not getting the correct voltage, usually 115 V AC, then the primary control and wiring should be checked.

If the transformer is receiving the correct voltage, check the output of the transformer with a high-voltage probe. Turn the power off, swing the transformer up, turn the system on, and check the output terminals with a special probe made for the 10,000 V secondary winding. If the voltage is less than the transformer rating, usually 10,000 V, the transformer must be replaced.

Primary Control Problems

The burner should be operating if the primary control is receiving 120 V, the circuit is closed across the two T terminals, and the primary control has not tripped. An easy way to test the primary control is to jumper the T terminals (Figure 56-4). The burner should start, and after lighting it should stay on. If the primary control trips out even though a flame is present, the problem could be in either the primary control or the cad cell.

After starting the burner, connect the leads to jumper the F terminals to test the cad cell. This will act to bypass the cad cell. If the control still trips out, it cannot be the fault of the cad cell so the primary control is bad. If the burner continues to fire, disconnect the cad cell and check its resistance. When a flame is established, the light strikes the cad cell and immediately reduces the resistance of the cell from over 10,000 Ω to about 1,500 Ω or less. A good reading would be between 300 and 1,000 Ω . If the resistance is over 1,600 Ω , the cad cell is misaligned, dirty, or defective.

If the reading is high, turn off the burner and recheck the cad cell resistance with no flame present. It should rise to 100,000 Ω or more. While the burner is off, clean the cad

Figure 56-4 Primary control T terminals.

cell and check its alignment. Start the burner again and recheck the cad cell resistance with the flame established. If the cad cell still has too high a resistance, replace it.

56.3 OIL SYSTEM PROBLEMS

Not all problems are caused by the oil burner. The rest of the system, from the tank to the vent, can be the cause of system malfunctions.

Oil Tank–Related Problems

A common oil furnace problem is the lack of fuel. Check to see that there is fuel in the tank before spending a lot of time chasing down nonexistent problems. If the fuel tank is empty, the lines will need to be purged of air after the tank is filled. If the oil tank was emptied, it is a good idea to change the fuel-line filter, pump strainer, and nozzle. The last few gallons of oil are always the dirtiest, and filling the tank stirs up the sediment on the bottom. A new filter will help protect against future problems.

Suction-line leaks can cause two types of problems. On systems with oil safety valves, a suction leak may prevent the oil safety valve from opening, and this will shut off all oil flow. Even without the safety valve, suction leaks can introduce air into the oil. A frothy oil/air mixture is delivered to the pump, and uneven, dirty burning results.

If the vent on the oil tank is obstructed or plugged, the tank pressure can drop to the point that the fuel will not move.

Electrical Problems

Although oil furnaces are fairly simple to wire, they can still be wired incorrectly. If the furnace does not receive the proper voltage, nothing will operate. Modern furnaces with electronic control boards must be properly grounded and connected with the correct polarity. If the furnace is not grounded or the hot and neutral power wires are swapped, the furnace will not operate. This is usually indicated by a fault code from the diagnostic LED. On the control side, a bad thermostat or broken thermostat wire can cause the furnace to not operate.

Venting and Combustion Air Problems

Like any combustion appliance, oil furnaces need combustion air. In older leaky houses, combustion air is usually assumed to enter through infiltration, provided the furnace is located in an unconfined space. Newer houses should always have combustion air provided through grilles or ducts. It is never wrong to bring in combustion air, even with older houses. A lack of combustion air will cause poor combustion and can lead to carbon monoxide poisoning.

The draft regulator should be adjusted to maintain the correct over-fire draft, usually at least $-.02$ in wc draft. The vent connector should be as short and straight as possible. Long chimney connectors with lots of sharp turns will lead to poor venting and poor combustion. If the draft regulator cannot maintain the draft at the proper setting, the chimney connector may be the problem.

If the over-fire draft rises significantly after the indoor fan comes on, the heat exchanger is cracked. This is a dan-

gerous situation that should be corrected immediately. The furnace must usually be replaced if the heat exchanger is cracked. Heat exchangers are normally only changed under warranty.

Soot

An oil furnace that is not properly installed and maintained will produce soot. Soot is unburned carbon and oil that forms because of incomplete combustion. Soot can build to the point that heat exchangers and flues are clogged with it. When this happens, an extensive cleaning of the heat exchanger, chimney connector, and chimney is required. Soot buildup can lead to a condition called puff-back. This occurs when the combustion products cannot leave the furnace. Usually the incomplete combustion of the oil/air mixture is due to a blocked combustion chamber, leading to delayed ignition. When the oil does ignite, the small explosion produces a puff of soot and unburned oil forces its way out into the area around the furnace. This greasy black cloud leaves stains on surrounding areas. The way to prevent puff-back is to keep the furnace properly maintained so that soot buildup does not occur.

Fan Problems

If the burner runs but the indoor fan never comes on, the problem could be with the fan motor, the fan switch, or the primary control. If the fan motor is not operating, check the voltage to the motor. If the motor is not operating and it is receiving the correct voltage, it may need to be replaced. However, before replacing the motor, check the run capacitor. If the capacitor is good and the motor is still not running, replace the motor.

If the motor is not receiving voltage and the furnace has heated up, then the fan switch or primary control is bad. Some furnace fans are controlled by a temperature sensing bimetal fan switch (Figure 56-5). When the furnace heats up to the fan setpoint, the switch closes to start the fan. When the furnace temperature drops below the fan setpoint, the switch opens to stop the fan. Other furnaces use primary controls that bring the fan on using a time delay relay.

56.4 OIL FURNACE TROUBLESHOOTING PROCEDURES

A good practice when troubleshooting oil furnace problems is to check the simple things first. This takes very little time and often saves lots of time and frustration.

- Check the fuel. Start by checking to see if there is oil in the tank and if the oil is clean.
- Make sure all valves in the fuel lines are open.
- Check the combustion chamber for unburned oil—better safe than sorry!
- Check the voltage to the furnace, including the grounding and polarity.
- Check to see that the thermostat is calling for heat. The furnace will not operate unless it is told to.
- Check to see if the primary control has tripped.

(a)

(b)

(c)

Figure 56-5 (a,b) Combination fan and limit control switch located above burner; (c) bimetal element connected to fan switch for sensing the furnace warm-air temperature.

Before starting the burner, check for liquid oil in the bottom of the combustion chamber. The customer knows that the burner should start if the reset button is pressed. If the reset button has been pressed a number of times, it is possible to have a considerable quantity of oil sprayed into the combustion chamber before the owner calls for help.

If any oil is pooling in the bottom of the combustion chamber, it must be removed by soaking it up with sponges or rags. When reaching into the combustion chamber, make sure that the power to the burner is off and your arm is covered. A fire extinguisher must be within reach and the observation door must be secured in the open position. When the flame is established, there will be a considerable fire developed until all of the oil has burned out of the bottom where it has soaked into the refractory. If the furnace is a large unit of 2.5 gph input or more, it is advisable to call the fire department to stand by before lighting the burner.

A manufacturer's troubleshooting logic chart can be useful for more difficult problems. Table 56-1 provides common causes of oil fired system problems.

Many of the solutions to the problems in Table 56-1 are evident when the cause is determined. The following list of remedies from 1 through 7 provides further information. The numbers refer to the references in Table 56-1.

TECH TIP

Listen to the customer's comments carefully when talking with them. Their description may shed light on the problem. But more important, being interested in the customer and their concerns is a big part of a technician's job. Displaying a lack of interest in the customer's concerns will alienate the customer. Alienating the customer can result in their loss of confidence in you and your company. Ultimately, this results in reduced income for you.

1. Protector Relay Defective

There are two types of protector relays: a cad cell that operates the relay from the light of the fire and a bimetallic control in the hot flue gases of a smoke pipe mount.

Cad cell This type of protector relay uses a light-sensitive cadmium sulfide flame detector, as pictured in Figure 56-6, mounted to the firing tube of the oil burner. When the cell is exposed to light, its resistance is very low, which allows current to flow through it. This current is sufficient to pull in the sensitive relay in the protector relay.

When the relay pulls in, it opens the circuit to the safety switch heater and prevents cutout of the burner. If the cell is not exposed to the light of the fire or if the cell becomes dirty or covered with soot, then it will not allow the current to pull in the sensitive relay; the safety switch heater remains in the circuit until the safety switch opens. This breaks the thermostat circuit and the burner stops, as shown in the circuit in Figure 56-7.

TABLE 56-1 Oil System Problems

Problems	Possible causes (see the Following Number References for Further Information)	Problems	Possible causes (see the Following Number References for Further Information)
Will not start	Season switch open Room thermostat improperly set Safety switch open on protector relay Fuse blown Limit control open Protector relay transformer defective (1) Protector relay defective (2)	High fuel cost	Improper input Improper burner adjustment
		High electric cost	Improper load on blower motor
		Smoke or odor from observation door	Improper draft or draft control setting Improper venting Improper input Delayed ignition
Starts, but will not continue to run		Burner pulses	Improper draft Improper venting
A. No fire established	No fuel (6) No ignition Protector relay not functioning Nozzle defective Fuel pump defective	A. No fire established	Burner cuts off on safety switch No fuel No ignition Protector relay defective
B. Fire established	Defective oil burner component Defective protector relay	B. Fire established	Components of burner defective
Runs, but short-cycles	Improper heat anticipator setting Cycling on limit control	Delayed ignition	Components of burner defective Carbon deposit on firing head
Runs, but room temperature too high	High setting of thermostat Improper heat anticipator setting		Improper electrode adjustment (3) Cracked electrode insulator (4)
Runs continuously	Short in thermostat circuit Stuck contacts in protector relay		Ignition leads burned out Ignition transformer burned out (5)
Blower cycles after thermostat is satisfied	Incorrect blower CFM Incorrect fan control setting Heat exchange heavy with soot	Burns inside burner after cutoff	Fuel unit defective
Blows cold air on start	Incorrect blower CFM Incorrect fan control setting	Carbon deposits on refractory	Defective nozzle
Start-up/cool-down noise	Expansion noise in heat exchanger Duct expansion	Noisy flame	Improper air adjustment Improper nozzle
Noise/vibration	Burner pulsation Blower wheel unbalanced Blower drive problems	Fuel pump sings Heat exchanger burnout	Fuel unit defective (7) Input too high Defective refractory Defective nozzle
Odor	Oil odor on unit start-up Improper venting Cracked heat exchanger	Blower short-cycles	Input too low Blower CFM too high Fan control defective

Figure 56-6 The ignition transformer cover is swung open to access the light-sensitive cadmium sulfide cell for one style of burner.

The safety switch is manually reset. When checking the protector relay for repeated burner cutoff even though the flame is established, make sure that the cad cell is clean. The cad cell can also be checked using an ohmmeter. Connect the ohmmeter leads across the leads of the cad cell. For a properly adjusted burner during operation, the cad cell resistance should be approximately 300–1,000 Ω but not more than 1,600 Ω . Understand that this is the expected resistance when the cad cell is exposed to a bright flame. The reading measured from exposure to room lighting or a flashlight will be different. Placing a finger over the cell, cutting off the light, will raise the resistance to 100,000 Ω or higher.

SERVICE TIP

When replacing a cad cell, be sure that it is completely and squarely seated. If the cad cell is not seated properly, it might not be “looking” at the flame, so it will not operate properly. An improperly seated cad cell can be the cause of an intermittent problem.

If the cad cell checks out, check the protector relay by placing a jumper wire across the F-F terminals of the protector relay. The burner should start and continue to operate. If it cuts off, the timer contacts and heater circuit are defective, and the relay should be replaced.

Bimetallic controls This type of control is clutch-operated to move the hot and cold controls through their proper sequence. Any sharp blow to the control can release this clutch and throw the control out of sequence. The clutch also wears and can loosen the hold on the contact fingers.

If the control refuses to operate, pull the drive shaft lever forward until the stop is reached. Slowly release the drive shaft lever to the cold position. This should close the contacts and the unit should operate. If not, the bimetallic element could be jammed or the contacts could be defective. To check the bimetallic element, remove the protector relay from the vent stack and check it. Usually carbon (soot) buildup through the bimetallic helix will be the cause of jamming the drive shaft lever. When cleaning the helix, be careful not to bend or break it. With a clean helix, if the hot and cold contacts still do not hold, then the clutch and contact leaves are worn and the entire control should be replaced.

SERVICE TIP

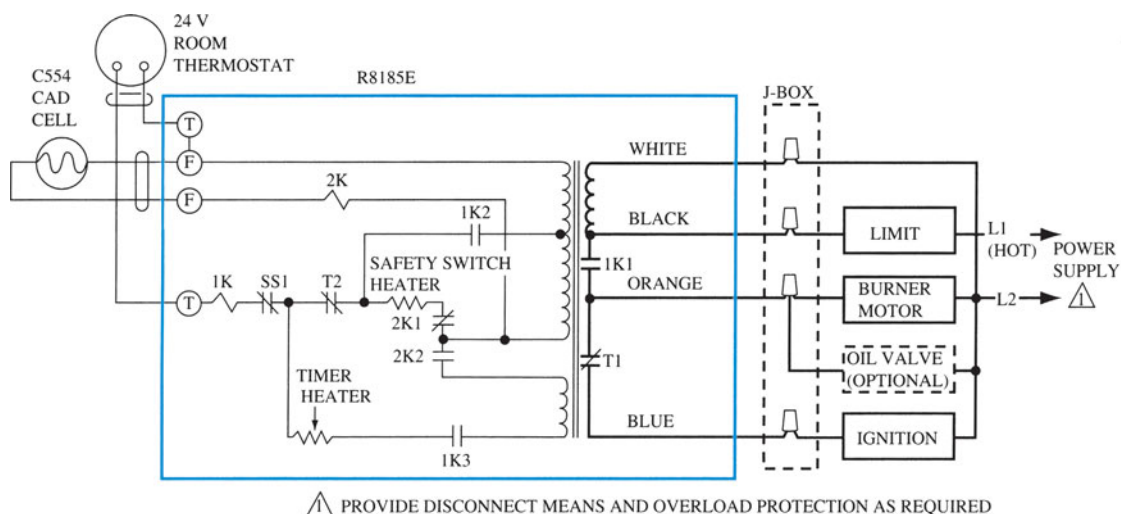

If a bimetal helix is not operating smoothly after cleaning, it must be replaced. Any slight roughness in operation will only get worse and will result in a recall to the residence to fix the problem later.

2. Protector Relay Transformer Burned Out

It is usually not possible to open the protector relay to reach the transformer to test it. It is not necessary since connections to the transformer are done through the T-T terminals on the outside terminal board.

Figure 56-7 shows the inside wiring diagram of a typical protector relay circuit. The control circuit is completed from the top terminal T through the transformer, the normally

Figure 56-7 Oil burner wiring schematic diagram using cad cell protector relay.

closed contact (2K1), the safety switch heater, the normally closed contact (T2), the safety switch (SS1), and the relay coil (1K) to the bottom terminal T. With the control wires removed from terminals T-T, 24 V should be measured across them when there is 120 V across the white and black leads to the relay. If there is no voltage measured at T-T, replace the protector relay. If there is voltage at T-T and the thermostat will not operate the relay, check the thermostat and sub-base on the control cable.

3. Improper Electrode Adjustment

To establish the spark necessary to ignite the oil, the electrodes have to be close enough together to present a minimum gap resistance to the 10,000–15,000 V supplied by the ignition transformer. The size of the gap between the electrodes is normally set at a distance of $\frac{1}{8}$ in. The electrodes must be positioned out of the oil spray but still have the arc flame close enough for ignition. The electrodes must be positioned at the proper height above the hole in the nozzle tip and at the proper distance ahead of it. These dimensions will vary between different burner types.

Another measurement, called the Z dimension, is the distance from the nozzle tip to the end of the firing-tube air turbulator. If the distance is too close, then oil spray can impinge on the turbulator and lead to carbon buildup. If the distance is too far, then the nozzle will be exposed to more heat from the furnace. The nozzle should be positioned back far enough to keep the effect of the heat from the fire to a minimum.

4. Cracked Electrode Insulators

The electrodes are held in place by clamps to ensure stability in the proper position. Where the clamps are fastened, a ceramic insulator surrounds each electrode to insulate the spark voltage from the grounded assembly. The ceramic must insulate against 5,000–7,500 V (one-half the spark voltage) and still stand up against the heat of the burner.

Never overtighten the electrode clamps, because the ceramic insulators are hard and brittle and crack easily. Loosen the electrode clamps before applying any twisting or bending pressure to change the position of the electrodes. Do not attempt to bend the electrode wires because they are harder than the ceramic.

SERVICE TIP

If any fine cracks (often referred to as crazing) are noted on the surface of the insulators, replace them. Do not take a chance on the old ones.

5. Ignition Transformer Defective

Ignition transformers are 10,000–15,000 V with a grounded center tap on the high-voltage side. With 12,000 V between the terminals and 6,000 V from either terminal to ground, attempting to check the transformer by producing a spark with a wire, screwdriver, or other shorting means can be dangerous.

In time, the heat of operation dries the transformer, and cracks develop. Moisture enters the assembly and is absorbed into the windings. This leads to shorts between

Figure 56-8 Transformer test wiring diagram.

the windings, which lower the output voltage to the point of failure of the spark across the ignition gap, and faulty ignition results.

The best way to check a transformer is with a high-voltage meter in the range of 10,000 to 15,000 V. If this meter is not available, two 120 V voltmeters and a new ignition transformer can be substituted. This transformer needs to have the same input and output voltage rating as the transformer being tested. Figure 56-8 shows the wiring diagram for this test.

The secondary of each of the transformers (high-voltage terminals) are connected together. The new transformer will step down the voltage output of the transformer being tested. With 120 V applied to the test transformer (measured with one of the voltmeters), the output of the new or testing transformer should be within 10 percent of the applied voltage. In addition, the output voltage should hold steady. If there is more than a 10 percent difference or if the output voltage varies, the original transformer has internal shorts and should be replaced.

6. No Fuel

Before taking the burner apart, first check the quantity of oil in the supply tank (the oil gauge on the inside tank or the dip rod for the outside buried tank). Second, close the tank outlet valve, open the filter cartridge case, and put in a new filter cartridge. Bleed the air from the filter cartridge after assembly. Third, after replacing the filter cartridge, make sure that the tank outlet valve is open.

If this procedure still does not supply oil to the burner and produce fire, remove the oil burner nozzle and check the nozzle filter. If this is plugged, replace the entire nozzle assembly with one of like capacity, spray angle, and cone type.

SERVICE TIP

If the oil filter or oil strainers are plugged with rust, the oil storage tank must be cleaned or replaced. A dirty oil storage tank will continually cause the filter and strainers to be plugged, resulting in numerous callbacks.

If these steps do not produce oil flow when the unit runs, check the inlet screen of the fuel pump. Inside the unit is located a fine mesh screen filter at the inlet to the pump assembly. This screen can be removed and replaced. Do not leave this screen out of the unit.

After any part of the fuel supply system has been opened, the system must be purged of air. A two-pipe system will automatically purge itself of air. The single-pipe

gravity feed system does not have an automatic purge feature. To purge a single-pipe system, connect a short piece of plastic hose from the bleed valve located on the side of the fuel unit. Allow the plastic hose to drain into a suitable container. With the bleed valve open, run the furnace until a clean stream of fuel oil is emitted from the hose. It may be necessary to reset the protector relay safety switch several times before the supply line is completely purged.

If it is not possible to obtain a flow of clear fuel oil, it is possible that the fuel unit is drawing in air through a line or fitting leak. If this is the case, then the leak must be located and corrected.

7. Fuel Unit Poor Cutoff

The most common problem in fuel units is poor cutoff of the oil supply when the unit cycles off. Correct cutoff will provide instantaneous cutoff of the oil to the fuel pipe and nozzle when the pump pressure drops to 80 percent of the operating pressure. At 100 psig operating pressure, the cutoff pressure is 80 psig. This is accomplished as the spring forces the control piston in the fuel unit against the fuel outlet seat and cuts off the flow of oil. The nozzle pressure drops immediately.

If particle buildup occurs on the face of the neoprene seat on the end of the piston, this prevents full-circle contact of the neoprene disk against the seat. Instead of positive cutoff, leakage occurs and the pressure gradually decreases in the nozzle. This gradual pressure reduction causes oil flow from the nozzle after the unit stops and the air supply disappears. The oil now burns with very little combustion air, producing a very smoky flame.

Carbon builds up on the turbulator end of the firing tube as well as the firing assembly. If the burner is not slanted at least 2° downward toward the combustion chamber, burning oil can flow back toward the blower. This can burn or smoke up the cad cell, with resulting cutoff of the burner on the safety switch. The correction for this is to clean the piston chamber of the fuel unit as well as the intake screen.

A persistent cause of this problem due to the quality of fuel oil supply can be reduced by double filtering the oil before it reaches the unit and using a delayed-action oil valve, as shown in Figure 56-9.

Figure 56-9 Delayed-action oil valve used with fuel unit.

Located in the fuel line between the outlet of the fuel unit and the firing head, a delayed-action oil valve provides a time delay between the blower starting and the start of oil spray. This ensures that air for combustion as well as airflow through the heat exchanger are established before combustion starts. The valve also provides instant cutoff of oil pressure to the nozzle, regardless of the action of the fuel unit. This is a highly recommended accessory for any oil-fired unit.

UNIT 56—SUMMARY

Remember when troubleshooting oil heating furnaces that the entire system is important, not just the burner. Problems in the oil supply or vent can shut the system down just as readily as problems with the burner. Try not to overlook the obvious: many oil furnaces quit heating because they run out of oil. Work safely. When the problem is related to the burner, remember to always check the combustion chamber for oil anytime the primary control is tripped when you arrive. Also remember that the output of the ignition transformer is 10,000 V and is more than capable of causing you serious harm.

WORK ORDERS

Service Ticket 5601

Customer Complaint: No Heat

Equipment Type: 80 Percent Oil Furnace with Standard Burner

A technician answers a service call for an oil furnace that is not heating. Upon inspection, the first thing that the technician finds is that the primary control safety has tripped. The first step taken is to shut off the power supply to the furnace and check the combustion chamber for oil. Fortunately, the combustion chamber is dry.

After completing this first safety check, the technician resets the primary control and starts the furnace. There is the normal buzzing sound coming from the ignition system but an unfamiliar fluttering noise coming from the burner. The furnace does not fire and the primary control trips out. The technician once again checks the combustion chamber and finds that it is still dry, indicating that most likely no fuel had passed through the nozzle.

Given this, along with the fluttering noise, the technician suspects the problem to be in the fuel unit. Inspecting the oil pump, it is found that the coupling is stripped so that the pump is not turning as it should. The technician replaces the coupling and installs a pressure gauge to monitor the pump pressure. Pushing the reset, the burner fires and the gauge shows that the operating pressure is 100 psig.

Service Ticket 5602**Customer Complaint: Poor Heat****Equipment Type: 84 Percent Efficient Lowboy Oil Furnace**

The furnace is running when the technician arrives to answer a call for an oil furnace that is operating but with poor heat output. It is immediately apparent that the furnace flame is unsteady. The technician conducts a smoke spot test and finds that there is enough soot to produce a No. 3 smoke spot.

A pressure gauge is installed to monitor the pump pressure, and it is fluctuating between 85 psig and 95 psig. A check of the pressure on the suction line reveals a vacuum of around 18 in Hg. This vacuum is much too high given that the oil tank is located in the basement with the furnace. The furnace is shut off to allow the filter on the fuel unit to be checked, and it is found to be extremely clogged. The technician not only replaces the filter but also the nozzle, because it will also prove to be partially blocked. The furnace is started, and now the suction vacuum is around 2 in Hg and the output pressure is 100 psig. The flames are steady and the smoke spot reading drops to No. 1.

Service Ticket 5603**Customer Complaint: Poor Heat****Equipment Type: 86 Percent Efficient Oil Furnace with Flame-Retention Burner**

Arriving at a house for a poor-heat call, the technician immediately notices smoke coming from the chimney and the distinctive odor of unburned fuel oil. Upon inspection, the technician finds that the furnace is operating but putting out very little heat. The flame pattern is ragged and the color is not uniform but streaked.

The furnace is shut off and the combustion chamber is inspected. It is found to be full of soot. Another thing the technician finds is that the retention ring is missing from the burner. It is in the bottom of the combustion chamber covered in soot. The technician explains to the customer that without the retention ring in place, the burner cannot properly mix the fuel and air, so a low-temperature, sooty flame is the result. The customer is also informed that besides replacing the retention ring, the heat exchanger, chimney connector, and chimney will all need cleaning before the furnace can operate safely again.

Service Ticket 5604**Customer Complaint: No Heat****Equipment Type: Standard 80 Percent Efficient Oil Furnace in Auto Garage**

A technician is called to a no-heat call on an oil furnace and finds that both the primary control and the burner motor overload have tripped. The technician checks for oil in the combustion chamber and finds it dry. The

burner motor overload and primary control are reset and the furnace begins to start. The burner motor makes a loud hum and trips out again along with the primary control.

The technician turns off the power and then tries to turn the combustion blower by hand. It will not turn freely. The drive coupling is removed from the pump and the blower is turned once again. Now the motor and fan turn freely, so evidently the oil pump is locked up. The technician also finds that the fuel filter is very dirty and it has an unusual black, tarry look to it. This leads the technician to talk to the customer about the fuel supplier.

After a brief discussion, the customer confesses that he has been pouring used motor oil into the oil tank. The technician politely explains that the furnace is not designed to burn used motor oil and now the furnace needs a new oil pump, a new nozzle, and a new filter. The heat exchanger and chimney will need to be cleaned. In addition, the oil tank should be drained and the lines flushed. The customer asks if there is any alternative, and the technician explains that furnaces are available that are designed to operate on used oil. The technician sets up an appointment for the customer with a company sales representative.

Service Ticket 5605**Customer Complaint: No Heat****Equipment Type: Oil-Fired Hydronic Boiler**

Upon arriving, the technician finds that the primary control has tripped. So first the combustion chamber is inspected for oil. As to be expected, a puddle of oil is found on the bottom of the combustion chamber and is cleaned out. After this, the technician disconnects the nozzle line connector and directs it toward a container. When the primary control is reset, the burner comes on. A clear steady stream of oil shoots into the container, but no characteristic buzz is heard from the electrodes.

The nozzle line connector is replaced and the wires to the burner motor are disconnected. The technician starts the furnace again and this time tests the transformer output with a special high-voltage probe. The transformer is not producing any secondary voltage. The technician turns off the power and measures the resistance of the secondary winding. The reading shows an infinite resistance, indicating it is open. After changing the ignition transformer and checking the electrode gap, the boiler is started and found to run correctly.

Service Ticket 5606**Customer Complaint: No Heat****Equipment Type: 84 Percent Efficient Oil Furnace with Flame-Retention Burner**

When the technician arrives, the furnace is not operating and the primary control has tripped. A check of the combustion chamber shows no accumulated oil.

The technician starts the furnace, it lights, and a short while later the primary control trips and the furnace shuts down.

The technician disconnects the cad cell, resets the primary control, and jumpers the F terminals once the burner has lit. This time the furnace remains firing and the cad cell resistance is measured to be 20,000 Ω . The resistance is too high so the cad cell is cleaned and then checked to make sure it is positioned correctly. Even so, the resistance reading remains high, and this indicates that the cad cell needs to be replaced. The technician replaces the cad cell and the furnace lights and stays running.

UNIT 56—REVIEW QUESTIONS

1. What is indicated by a frothy stream of oil in the oil supply line?
2. List the general types of oil furnace problems.
3. How can the cause of a locked burner motor be determined?
4. How can a defective ignition transformer be diagnosed?
5. What are some common types of ignition system problems other than a defective ignition transformer?
6. What are the symptoms of a defective oil pump drive coupling?
7. What are the symptoms of an oil pump with a leaky shutoff?
8. What resistance readings indicate a good cad cell?
9. What causes soot buildup?
10. What is puff-back?
11. What safety precaution should be followed when working on a furnace with a tripped primary control?
12. According to Table 56-1, what can cause carbon deposits on the refractory?
13. List some types of oil pump problems.
14. When should an oil pump internal bypass plug be removed?
15. How can a leak in the fuel suction line cause no oil to be delivered to the pump?
16. What two methods are used to control the indoor fan?
17. According to Table 56-1, what are some causes of a short-cycling indoor blower?
18. Provide a list of preliminary checks when troubleshooting oil furnaces.
19. What unique problems can arise in oil furnaces because oil is a liquid fuel?
20. What two manual resets do all oil burners have?

UNIT 57

Space Heaters

OBJECTIVES

After completing this unit, you will be able to:

1. list the different types of gas space heaters.
2. list the different types of electric space heaters.

3. explain which type of space heater is best suited for a specific application.
4. determine the best location for an infrared-type space heater.

57.1 INTRODUCTION

A space heater is used to heat a dedicated space rather than to supply heat for the entire building. There are a wide variety of types, with some being portable while others are permanently installed in the space. Space heaters employ a combination of radiation, natural convection, and forced convection to transfer the heat produced. The energy source may be liquid, solid, gaseous, or electric. Space heaters are often used for garages, workshops, and utility rooms that may not be a part of the regular house heating circuit. They are also popular in applications where heat is to be used only on a periodic basis, such as for a vacation home. Industrial space heaters can be used to heat a warehouse by staggering them at different locations throughout the building with each unit heating a specific area. Space heaters are designed to be easily installed and operated, and due to the variation in their type and flexibility, they are commonly used for many different applications.

57.2 GAS ROOM HEATERS

Gas room heaters are self-contained, freestanding units that transfer the heat produced from fuel combustion to room air through a heat exchanger system. The heat is transferred by radiation and convection without mixing the flue gas with the circulating room air. Since air for combustion is supplied from the room air, these units must be installed in a space that has sufficient infiltration to supply the necessary combustion air. Room heaters are made in a number of different constructions: vented, unvented, and catalytic.

TECH TIP

Many local codes do not allow unvented space heaters to be used in many occupied areas. This may mean that when replacing an unvented space heater with new equipment, a vented space heater may need to be used. The primary concern for unvented space heaters is the oxygen depletion and possible carbon monoxide buildup. For that reason, it is strongly recommended and may be mandated by ordinance that carbon monoxide detectors be located in any area where unvented space heaters are being used.

Vented Room Gas Heaters

Vented room gas heaters have an opening that is permanently connected to the chimney to convey the flue gas to the outdoors. The combustion gases pass through a heat exchanger that transfers the heat to the room air by radiation and convection. Cool room air enters the grille at the bottom of the unit and the heated air is distributed from the top. These heaters often have a glass panel on the front to supply radiant heat. Room air is completely separated from the combustion gases.

Some room heaters are operated entirely by gravity. Others use a fan to circulate the room air through the unit. The fan increases the efficiency of the heater and provides better distribution of the heated air. Since the air for combustion is taken from the room, applications are limited to spaces where there is sufficient infiltrated air to supply the required combustion air. These units are available in sizes of 10,000 to 75,000 BTU/hr.

Unvented Room Gas Heaters

Unvented room gas heaters discharge the products of combustion into the room. They are limited in application to commercial projects where the area is relatively open. They are often used during building construction to supply temporary heat. One type commonly used is called a "salamander." It is portable and can be located where needed.

Catalytic Room Gas Heater

The catalytic heater transfers heat from a glowing heat exchanger. It has no flame. The heat exchanger is constructed of fibrous material impregnated with a catalytic substance that accelerates the oxidation of a gaseous fuel. Catalytic heaters transfer heat by radiation and convection. The surface temperature is below red heat, usually about 1,200°F.

57.3 GAS WALL FURNACES

Gas wall furnaces are designed in a vertical configuration to fit into the stud space. They heat a single room or have a rear boot to also supply heat to an adjacent room. The units are usually 6 or 8 in deep, so that part of the cabinet protrudes into the room. The units are completely self-contained and

Figure 57-1 Direct vent for gas heater.

operate from a room thermostat. Some units have gravity air circulation, while others use a small blower. Some units have conventional venting arrangements with a flue extending above the roof. Others, located on the outside wall, have direct vents.

The installation of a direct-vent unit requires one penetration to be made through the exterior wall. The exhaust and intake are a double-pipe configuration (Figure 57-1).

For small gas space heaters, the direct-vent connection is often supplied with the unit (Figure 57-2a-d). The gas connection and operation are similar to regular gas furnace types. A typical sealed combustion chamber and igniter are shown in Figure 57-3. These units pull the air for combustion from the outside and therefore can be placed in a tight room. Heating capacities are available from 6,000 to 65,000 BTU/hr.

(a)

(b)

Figure 57-3 (a) Sealed combustion chamber for small gas space heater; (b) igniter for gas space heater.

57.4 GAS FLOOR FURNACES

Gas floor furnaces are constructed for suspension from a floor. The unit is constructed for supplying heated air through the center of the grille, with the return air entering through the outside corners. Combustion air is drawn from the outside of the building. The common application of these units is in a central room of a small house, where often a single unit is used to circulate heated air through the entire house.

SERVICE TIP

Some wall furnaces and floor furnaces use micro-voltage thermostat and gas valves. These units are typically ones that do not have circulating blowers, so there is no need to supply line voltage to the furnaces. The voltage to operate the system comes from a thermopile. A thermopile is much like a thermocouple except that it generates between 600 and 800 mV, which is significantly more than the 20 to 30 mV produced by a thermocouple. The thermopile's voltage is enough to operate the gas valve. Because the operative voltage is so slight, any loose connections in the control wiring can cause the system to fail to operate.

Table 57-1 Gas-Fired Direct Heating Equipment Efficiency Requirement

Heater Type	Input (BTU/hr)	Standard Level
Wall fan heaters	up to 42,000	AFUE = 75%
Wall fan heaters	over 42,000	AFUE = 76%
Wall gravity heaters	up to 27,000	AFUE = 65%
Wall gravity heaters	27,000 to 46,000	AFUE = 66%
Wall gravity heaters	over 46,000	AFUE = 67%
Floor heaters	up to 37,000	AFUE = 57%
Floor heaters	over 37,000	AFUE = 58%
Room heaters	up to 20,000	AFUE = 61%
Room heaters	20,000 to 27,000	AFUE = 66%
Room heaters	27,000 to 46,000	AFUE = 67%
Room heaters	over 46,000	AFUE = 68%
Hearth heaters	up to 20,000	AFUE = 61%
Hearth heaters	20,000 to 27,000	AFUE = 66%
Hearth heaters	27,000 to 46,000	AFUE = 67%
Hearth heaters	over 46,000	AFUE = 68%

57.5 GAS HEATER MINIMUM EFFICIENCY REQUIREMENTS

The National Appliance Energy Conservation Act of 1987 established minimum efficiency requirements for all gas-fired direct heating equipment (Table 57-1). The AFUE values are obtained by the test methods set up by the Department of Energy.

57.6 GAS HEATER CONTROLS

The requirements for gas space heater controls are different from conventional furnaces. Since a space heater is located in the room, a wall-mounted thermostat is more often an option as compared to a thermostat that is built directly into the heater.

Wall Thermostats

These thermostats can be either 24 V or use millivolt power for thermopile-type gas heaters. They are selected to operate whatever gas valve is being used. A suitable source of power must be supplied.

Built-in Hydraulic Thermostats

These are made in two types: a snap-action two-position thermostat with a liquid-filled capillary-tube temperature-sensing

Figure 57-4 Gas fired infrared heater for large building or warehouse.

element, and a modulating-type thermostat, similar to the first type, except the temperature alters the position of the gas valve between off and fully open.

57.7 GAS-FIRED INFRARED HEATERS

A typical gas-fired infrared heater installation for a warehouse or large open area is shown in Figure 57-4. Heaters are located overhead and radiate heat to the area below. By using radiation, heat is directed to the people and objects in the spaces that require warming, rather than wasting it to the air or other nonessential surfaces. This makes possible maintaining lower room temperatures, yet creating comfortable conditions and saving energy.

An operating heater is shown in Figure 57-5. Individual burners of this type can range from 20,000 to 120,000 BTU/hr, fired in series, with branches connected to one induction blower. These systems are custom engineered to meet specific floor plans as well as heating requirements. They can be operated in a condensing mode for the ultimate in heating efficiency. Direct-spark ignition is used. Combustion chambers can be either fabricated steel or optional cast iron. The tailpipe is porcelain lined.

Figure 57-5 Gas fired infrared heater in operation..

Figure 57-6 High-intensity infrared heater.

A factory-assembled control panel combines pre-purge and post-purge controls. Connections are provided for up to four low-voltage thermostats for zone temperature control. Units are fully vented to avoid release of combustion moisture inside the building. An optional controller continuously monitors the demand for heat and adjusts firing cycles. Automatic setback can be programmed for nights, weekends, and holidays.

High-intensity infrared heaters using natural gas or LP are also available for direct radiant heating, Figure 57-6.

57.8 VAPORIZING OIL POT (KEROSENE) HEATERS

Vaporizing-type oil-burning units use grade 1 fuel oil (kerosene). The oil is burned in a bowl or pot. A constant level metering device, with an adjustable needle, controls the flow of oil into the combustion chamber and pilot burner through a burner oil supply pipe. The adjustable needle can be manually placed in an OFF, PILOT, or VARIABLE FLOW setting. The oil flows by gravity from a 2- or 3-gallon tank attached to the unit or a larger tank located outside.

Oil is vaporized by the heat of combustion and by contact with the hot metal surfaces of the combustion chamber. The combustion air enters from the room and mixes with the vaporized oil. Units can be supplied for gravity air circulation or with an air circulator. A port opening for cleaning the unit and for access for lighting the pilot is provided on the front of the drum-type heat exchanger. An automatic draft controller is used on the flue pipe to maintain the required draft. Flue gases are vented to the outside. A perforated metal grille is located on the lower front of the cabinet to admit return air for heating. The supply of heated air enters the room from the top of the unit. The steel heat exchanger furnishes radiant heat to the room by heating the side walls of the cabinet. A thermostat can be used to operate the unit by turning on and off the unit at a selected firing rate.

57.9 ELECTRIC IN-SPACE HEATERS

There are various types of electrical in-space heaters. Because there are no products of combustion and no flue, their location is very flexible.

TECH TIP

Although electric heat is the most expensive type for heating, it is the least expensive as far as equipment and maintenance are concerned. Electric space heaters are ideal for applications such as sunrooms, vacation homes, and other areas where heating would only be used on a limited basis. Electric space heaters can sit for long periods of time unused and still function reliably.

Forced-Air Electric Heaters

Forced-air electric heaters add a measure of comfort to electric space heating. In homes and offices, the recessed models combine style with the forced-air circulation, resulting in more uniform room temperature control. Most are wall mounted, but models are also available for recessing into the ceiling and even under kitchen counters. Wall-mounted units provide up to 3,000 W (10,240 BTU/hr), which can warm larger rooms or offices.

Suspended-Force Fan-Unit Electric Heaters

Suspended-force fan-unit electrical heaters are most functional for garages, workrooms, and playrooms where large capacity and positive air circulation are important. These are also popular in commercial and industrial establishments of all kinds. They may be suspended in vertical or horizontal fashion, as shown in Figure 57-7, with a number of control options, such as wall switch only, thermostats, timers, and night setback operation. Capacities generally range from 3 to 12 kW and above. Discharge louvers may be set to regulate air motion patterns. The heavy-duty construction of this heater category is geared for commercial application.

Cabinet-Type Electrical Space Heaters

Cabinet-type electrical space heaters are found in classrooms, corridors, foyers, and similar areas of commercial and institutional buildings where cooling is not a consideration. Heating elements go up to 24 kW, and the fans are usually the centrifugal type for quiet but high volume airflow. Cabinets have provision for introducing outside air where use and/or local codes require minimum ventilation air.

Outdoor air intake damper operation can be manual or automatic. Control systems can be simple one-unit operation or multizone control from a central control station.

Figure 57-7 Suspended space heater.

Convection Baseboard Electrical Heaters

This is the most frequently used electric space heater for residential and commercial buildings. The heater provides for convective airflow across the finned-tube heating element. The contour of the casing provides warm air motion away from the walls, thus keeping them cooler and cleaner, as shown in Figure 57-8.

It is important that drapes do not block the airflow and cause overheating or that the carpeting block the inlet air. Most baseboard units have a built-in linear-type of thermal protection that prevents overheating. If blockage occurs, the safety limit stops the flow of electrical current. It cycles off and on until the blockage is removed. Baseboard heaters come in lengths of 2–10 ft in the nominal 120, 208, 240, and 277 V rating. Standard wattage per foot is 250 at the rated voltage. But lower heat output can be obtained by applying heaters on lower voltage.

For example, a standard 4-ft heater rated at 250 W/ft at 240 V will produce 1,000 W of heat. Most manufacturers offer these reduced-output (low density) models by changing

Figure 57-8 Baseboard space heater.

the heating element to 187 W/ft. Low density is generally preferred by engineers and utilities and is recommended for greatest comfort. Controls may be incorporated in the baseboard or through the use of wall-mounted thermostats. Accessories such as corner boxes, electrical outlets, and plug-in outlets for room air conditioners are available.

Electric Infrared Heaters

A multimount electric infrared heater has many applications, including total area heat, spot heat, and snow and ice control. They can be mounted horizontally, or at a 30°, 60°, or 90° angle. The double reflectors can be placed to provide a wide variety of patterns. Two elements are used per fixture. Three different lengths are available, and units

can be mounted end to end for additional lengths. Units are available in sizes of 3,200, 5,000, and 7,300 W. Any surface or object should be 24 in away from direct radiation from the unit. For mounting, UL requires fixtures to be at least 3 in from the ceiling and 24 in from a vertical surface. Rows of fixtures should be separated by a minimum of 36 in.

Electric Radiant Heating Cable

Electric radiant heating cable was one of the most popular methods of heating early in the development of radiant heating. It is an invisible source of heat and does not interfere with the placement of furnishings. The source of warmth is spread evenly over the area of the room. It can be installed within either plaster or drywall ceilings, as shown in Figure 57-9. Staples hold the wire in place until the finish layer of plaster or drywall is applied. Wall-mounted thermostats control space temperature.

Electric Heat Floor Panels

Electric heat floor panels can be constructed using perforated mats consisting of PVC-insulated heating cable woven in or attached to metal or glass fiber mesh. Such assemblies are available in sizes from 2 to 100 ft², with various watt densities ranging from 15 to 25 W/ft². Another effective method of slab heating uses mineral insulated (MI) heating cable. MI cable is small-diameter, highly durable, solid, electrical-resistance heating wire surrounded by compressed magnesium oxide electrical insulation and enclosed in a metal sheath. Several MI cable constructions are available, such as single conductor, double conductor, and double cable, as well as custom designed cables. Any of these constructions can be embedded in concrete.

Figure 57-9 Diagram showing installation of ceiling cable for radiant heating.

Figure 57-10 Room steam space heater.

57.10 STEAM SPACE HEATERS

Steam space heaters are used in applications where a ready supply of low-pressure steam is available. This type of heater is often suspended from the ceiling, as shown in Figure 57-10. The steam control valve is generally operated by a thermostat. The return line for the condensate will include a strainer and a steam trap. When this type of heater is used in a space that may fall below the freezing temperature, it should be turned on and operating. If the space is to be unheated for a period of time, a provision must be made for draining the heating coil. If the coil is not drained and freezes, the water inside will expand and split the coil. This type of damage is difficult to repair, and most likely the coil will need to be replaced.

UNIT 57—SUMMARY

There are many different types of space heaters available for different applications. Common types are gas or electric, but steam and kerosene-type heaters are also used. Direct-vent gas space heaters are fairly simple to install as there is no requirement for a chimney. Electric space heaters do not require any fuel and can be left for long periods without the need for layup or start-up maintenance. When considering the type of heater to install, consider the venting requirements, the availability of a fuel source, and the local code requirements. Larger space heaters may have repairable components, while smaller units may be designed for total replacement rather than repair. Space heaters are available in many different heating capacities, which allows them to be closely matched to the heating requirements for the space.

WORK ORDERS

Service Ticket 5701

Customer Complaint: Steam Leaking from Heater

Equipment Type: Steam Space Heater

The technician is told that steam began leaking from the heater when it was turned back on after the 3-week winter shutdown at the facility. The technician inspects the heater and then carefully opens the steam valve a small amount. Steam begins leaking out through a number of splits in the heating coil. The technician informs the facilities manager that the heater is beyond repair and needs to be replaced. It is also recommended that the coil be drained the next time a winter shutdown takes place.

Service Ticket 5702

Customer Complaint: Pilot Will Not Light

Equipment Type: Direct-Vent Gas Space Heater

The technician is told that the pilot will not light even though there seems to be gas available. The technician inspects the heater and asks if it has ever been cleaned before and is told it has not. The combustion chamber is removed and the rust that has collected inside the unit is vacuumed out and the thermopile and pilot are cleaned. Now the pilot lights normally and the unit works and provides the proper flame pattern.

Service Ticket 5703

Customer Complaint: Replacement Installation

Equipment Type: Unvented Gas Space Heater

The customer explains that the old gas space heater in the workshop needs to be replaced. It has worked well for many years, and an exact duplicate is preferred. The technician inspects the unit and explains that the local code no longer allows an unvented space heater to be used in an occupied area. This is because of the possibility of oxygen deprivation and possible carbon monoxide buildup. The customer complains that this will be more expensive if a chimney needs to be added to the workshop. The technician explains that a direct-vent-type gas space heater can easily be installed, and that would not require a chimney. It would only cost slightly more than the unvented gas heater to install. This would meet the code requirements and be much safer overall.

UNIT 57—REVIEW QUESTIONS

1. What is a restriction to be considered when installing a gas room heater?
2. What safety device should be installed where unvented space heaters are being used?

3. How does a vented room gas heater differ from an unvented room gas heater?
4. What is a "salamander"?
5. What type of gas space heater has no flame?
6. What is meant by a "direct-vent" heater?
7. Why do some gas furnaces not require an electrical power supply?
8. How do infrared heaters transfer heat?
9. What type of fuel does a vaporizing oil pot heater use?
10. How is the oil vaporized in a vaporizing oil pot heater?
11. What happens to an electrical space heater if it sits for long periods of time unused?
12. What is an advantage of a forced-air electric heater as compared to natural convection?
13. What type of electric space heater is used when large capacity and positive air circulation are important?
14. Where are cabinet-type electrical space heaters typically installed?
15. What is the most frequently used type of electric space heater for residential and commercial buildings?
16. How does a standard convection baseboard electrical heater compare to a low-density type?
17. How can electric infrared heaters be mounted?
18. What distance should an electric infrared heater be from any other surface?
19. How are mats for electric heat floor panels constructed?
20. What is mineral insulated (MI) heating cable?

UNIT 58

Humidifiers

OBJECTIVES

After completing this unit, you will be able to:

1. list the types of humidifiers.
2. recommend humidifiers that are appropriate for heat pump systems.
3. explain why humidification is needed in the winter.
4. describe humidifier maintenance procedures.
5. discuss humidifier control systems.

58.1 INTRODUCTION

Total comfort involves more than heating and cooling the air. In the heating season, the air is not truly conditioned until it has been humidified. Heating the air causes a natural decrease in relative humidity. Without humidification, the relative humidity in a heated house is similar to the Sahara Desert. Humidifiers that are not properly maintained will lose their effectiveness and can become a source of air contamination. Installing and servicing humidifiers is part of an air-conditioning technician's job description.

58.2 WHY HUMIDIFICATION IS NEEDED

The heated air in homes and buildings becomes dry during the heating season. The outdoor air cannot hold as much moisture at the lower temperatures. When the cold winter air is heated, the increased volume increases the air's ability to hold moisture, but the amount of moisture actually in the air remains the same. As a result, the relative humidity drops drastically.

This super-dry air sucks water out of everything it contacts, including people. This impacts comfort by making us feel colder and by drying out our mucous membranes. Other undesirable conditions that result from low relative humidity include increased static electricity and shrinking and cracking of wood furniture. Adding humidity to the air can also help save energy in the winter by promoting comfort at lower temperatures. It is desirable to maintain 30–60 percent relative humidity in the house. Figure 58-1 shows that many undesirable conditions that are detrimental to health are decreased between 30 and 60 percent relative humidity.

Air at 35°F and 100 percent relative humidity contains less water than air at 70°F and 30 percent relative humidity. Air at 35°F and 100 percent relative humidity contains 30 grains of moisture per pound of air. When air is heated to 70°F, it can hold 110 grains of moisture per pound. Thus, to maintain 50 percent relative humidity in a 70°F house, the grains of moisture per pound must be increased to 55 ($110 \times 0.5 = 55$). One pound of air entering a house from the outside will require the addition of 25 grains of moisture ($55 - 30 = 25$). The amount of infiltration depends on the tightness of the windows and doors and other parts of the construction.

Figure 58-1 Maintaining the relative humidity between 30 and 60 percent has numerous health benefits.

It is impractical in most buildings to maintain high relative humidity when the outside temperature is very low. Condensation forms on the inside of cold building surfaces when the surface temperature drops below the dew point of the air. This occurs first on the windows, but it can also occur inside the walls, contributing to rotting of walls from the inside out. For this reason, the recommended humidity level is lower for low outside temperatures than for higher outdoor temperatures. The amount of water that can be safely added to the air depends on the following:

1. Outside temperatures
2. House construction
3. Amount of relative humidity that the interior of the house will withstand without condensation problems

OUTDOOR TEMPERATURE	RECOMMENDED SETTING
-20°F	15%
-10°F	20%
0°F	25%
10°F	30%
20°F	40%
30°F	45%
40°F	50%

Figure 58-2 The recommended humidity setting is 50 percent at 40°F; the recommended setting decreases 5 percent for every 10°F decrease in outdoor temperature.

Figure 58-2 shows the recommended humidity levels for different outdoor temperatures.

58.3 TYPES OF HUMIDIFIERS

There are several types of humidifiers. Generally, the different types may be divided into two general classes: those that rely on heat in the air to evaporate the water and those that supply their own energy for evaporating the water. Humidifiers that require heat from the air for water evaporation include atomizing, evaporative, and bypass humidifiers. Vaporizing and steam humidifiers supply their own energy to evaporate the water.

The type of humidifier used depends upon the type of heating equipment and the amount of moisture needed. While all types of humidifiers will operate with furnaces, many types will not work well with heat pumps because the supply air is not hot enough to evaporate the water. Typically heat pumps require vaporizing, steam, or bypass humidifiers.

Humidifiers are typically wired to operate whenever the fan is operating during the heating cycle. They are usually controlled by a humidistat that senses the relative humidity of the return air. The wiring diagram shown in Figure 58-3 shows wiring with a single-speed fan motor. Vaporizing and steam humidifiers can be wired to operate whenever there

Figure 58-3 Wiring diagram for a humidifier with a single-speed motor.

Figure 58-4 Motorized atomized humidifiers can deliver 6–11 gal of water per day.

is a demand for more humidification. They can actually turn on the indoor blower and operate even if the heat is not operating.

58.4 ATOMIZING HUMIDIFIERS

Atomizing humidifiers work by spraying an atomized water mist into the airstream. Heat in the air then evaporates these small atomized droplets. Atomizing humidifiers typically require a 100°F minimum air temperature to operate. The water is atomized by either a motor that slings the water around or a spray nozzle that sprays a water mist directly into the duct. A motorized humidifier will not put more water into the air than it can evaporate, but these humidifiers can have a low capacity. Figure 58-4 shows a motorized atomizing humidifier.

The capacity of mister-style humidifiers is only limited by the nozzle size. However, it is easy to spray more water into the duct than the air can evaporate, making a mess. Mister humidifiers typically use a temperature sensor wired in series with the water solenoid to prevent spraying water into the duct when the air is not hot enough to evaporate the water (Figure 58-5). The nozzle has a built-in filter to prevent the nozzle from clogging (Figure 58-6). The nozzle should be changed annually to ensure correct operation.

58.5 EVAPORATIVE HUMIDIFIERS

Evaporative humidifiers provide a wetted surface that adds moisture to the heated air. There are three types of evaporative humidifiers:

- 1. Plate
- 2. Rotating drum
- 3. Fan powered

Plate Humidifiers

The plate evaporative humidifier has a series of porous plates mounted in a rack. The lower section of the plates

Figure 58-5 The mister will not energize the water solenoid until its thermostat senses that the air is warm.

Figure 58-6 Typical humidifier nozzle manufactured by Delavan. (Courtesy of Delavan)

extends down into water contained in the pan. A float valve regulates the supply of water to maintain a constant level in the pan. The pan and plates are mounted in the warm-air plenum. Plate humidifiers have a relatively low capacity compared to other humidifiers. The plates become brittle as mineral deposits from the evaporated water build in the plates. Annual maintenance includes changing the plates and cleaning the water sump.

Rotating-Drum Humidifiers

The rotating-drum evaporative humidifier has a slowly revolving drum covered with a polyurethane pad partially submerged in water (Figure 58-7). As the drum rotates, it absorbs water. The water level in the pan is maintained by a float valve. The humidifier is mounted on the side of the return-air plenum. Air from the supply plenum is ducted into the side of the humidifier. The air passes over the wetted surface, absorbs moisture, and then goes into the return-air plenum. Annual maintenance includes changing the drum pad and cleaning the water sump.

Figure 58-7 Rotating-drum humidifier.

Rotating Plate Humidifiers

The rotating plate evaporative humidifier is similar to the drum type in that the water-absorbing material revolves; however, this type is normally mounted on the underside of the main warm-air supply duct (Figure 58-8). Annual maintenance includes changing the plates and cleaning the water sump.

Bypass Evaporative Media Humidifier

The bypass-style humidifier is mounted on either the supply- or return-air plenum. A duct is run from the humidifier to the other plenum (Figure 58-9). When the fan runs, air

Figure 58-8 Rotating-plate evaporative humidifier.

Figure 58-9 In a bypass humidifier installation, air flows from the supply plenum, through the humidifier, and into the return plenum.

TYPICAL INSTALLATIONS

passes from the supply plenum, through the humidifier, into the return-air plenum. A manual damper is installed to shut off the bypass air when the system is operated in cooling.

Air passes over a media pad inside the humidifier. Typically, the media is expanded metal (Figure 58-10). A humidistat is used to control a water solenoid valve that controls the flow of water over the media. The control system is set up so that the humidifier can operate only when the furnace fan is running. This type of humidifier usually does not require much maintenance because the water is not recirculated and does not sit in a sump. The minerals left behind from evaporation are washed away with the drain water. However, it does use more water than other types with similar capacities because the water that is not evaporated washes down the drain.

Fan-Powered Evaporative Humidifier

The fan-powered evaporative humidifier is similar to the bypass type, except that it does not require bypassing air. It can be mounted on the return- or supply-air plenum, but its capacity is greater on the supply plenum. Air is drawn in by the fan, forced over the wetted core, and delivered back into the plenum (Figure 58-11). The control system is set up so that the humidifier can operate only when the furnace fan is running. The wiring for a fan-operated humidifier is shown in the diagram in Figure 58-12.

58.6 VAPORIZING HUMIDIFIERS

The vaporizing humidifier uses an electrical heating element immersed in a water reservoir to evaporate moisture into the furnace supply-air plenum (Figure 58-13). A constant level of water is maintained in the reservoir. These humidifiers can operate even though the furnace is not supplying heat. The

Figure 58-10 Expanded metal pad used in a bypass humidifier.

humidistat not only starts the water heater but also turns the furnace fan on if it is not running. These humidifiers have among the highest capacities of any type humidifier. They require more electricity than other types because the electrical element is heating water to 120°–160°F to increase the

Figure 58-11 Air is drawn in by the fan, forced over the wetted core, and delivered back into the plenum.

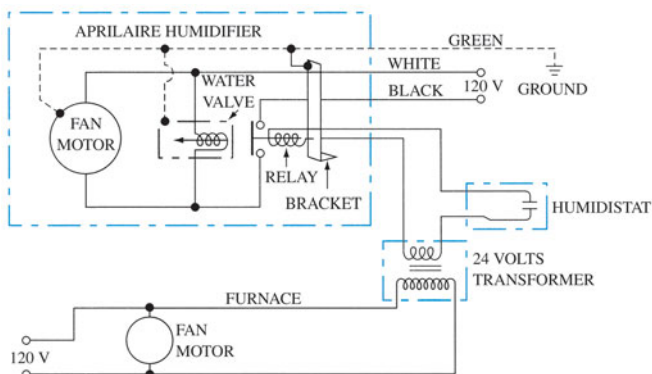

Figure 58-12 Wiring diagram for a fan-powered evaporative humidifier.

water evaporation. The power wiring required for vaporizing and steam humidifiers is much heavier than other types of humidifiers because of the increased electrical power needed to heat the water. Minerals from the water deposit on the element and in the sump, necessitating frequent cleaning. This type of humidifier often needs cleaning more than once a year. The heating element will burn out quickly if it is allowed to operate without water in the humidifier. These are both effective and simple, but frequent maintenance is absolutely essential.

Steam Humidifiers

The steam humidifier is a type of vaporizing humidifier (Figure 58-14). Steam humidifiers are ideal for use with systems like heat pumps, electric furnaces, high-efficiency furnaces, and furnaces using night setback thermostats that do not generate the high air temperatures necessary for evaporative humidifiers. The internal water temperature-sensing device

(a)

(b)

Figure 58-13 Vaporizing humidifier.

Figure 58-14 Steam humidifier.

operates the fan independently of the heating system. To reduce scaling and mineral deposits, some steam humidifiers have a flushing timer and chlorine-removal filters. The water in the unit is flushed out every 12 hours, removing accumulated solid materials.

SERVICE TIP

Mineral deposits are a problem with all types of humidifiers. When water evaporates, the minerals are left behind. This can be reduced by using filters in the water feeding the humidifier. Carbon filters can be used to remove chlorine from the water supply, thus eliminating the corrosive effects of chlorine on the unit. These filters also reduce mineral buildup.

SERVICE TIP

It is very important that humidifiers be regularly cleaned and checked for proper operation. The water sump in some types of humidifiers can grow algae and mold if not properly maintained. It is especially important to ensure that excessive moisture is not released into the house or duct system. Excessive moisture has been associated with mold growth, and mold growth is associated with poor indoor air quality.

58.7 HUMIDISTATS

A humidistat is used to control when the humidifier operates (Figure 58-15). Humidistats used with humidifiers open on an increase in humidity and close on a decrease in humidity. The setting of a humidistat can be changed to comply with changing outside air temperatures. If the set-

Figure 58-15 Typical humidistat for controlling a humidifier.

Figure 58-16 When too much moisture is added, the increased dew point causes water to condense on inside surfaces.

Figure 58-17 The clear nylon ribbon is the controlling element in this humidistat.

ting on the humidistat is too high, it may cause sweating on interior walls and windows (Figure 58-16). As it gets colder outside, the humidistat setting may need to be lowered.

The least expensive and most common humidistats are mounted on the return-air plenum. They typically use a nylon ribbon for sensing the humidity in the air (Figure 58-17). Better-quality humidistats use hair to sense humidity change (Figure 58-18). Hair shrinks when it gets wet and stretches when it dries. Several hundred hairs are stretched across a frame that controls the opening and closing of a set of points.

Some electronic humidity controls adjust themselves automatically to changing outdoor temperature. They sense the outdoor temperature and reset the humidity to a safe level for the outdoor temperature (Figure 58-19).

A few advanced electronic thermostats also incorporate humidity control. These controls can be used to control the total system operation, including humidification (Figure 58-20).

Figure 58-18 Hair is the controlling element of this humidistat.

UNIT 58—SUMMARY

Humidification is needed in the winter because heating the air reduces its relative humidity to desert levels. Humidifiers may be divided into two groups: those that rely on heat in

Figure 58-19 Advanced electronic humidity controller.

Figure 58-20 This thermostat incorporates humidity control in addition to temperature control.

the air to evaporate the water and those that supply their own energy for evaporating the water. Humidifiers that require heat from the air for water evaporation include atomizing, evaporative, and bypass humidifiers. Vaporizing and steam humidifiers supply their own energy to evaporate the water. Humidistats are used to control the operation of humidifiers. Mineral deposits are a common problem with many types of humidifiers. Humidifier service includes changing media and cleaning mineral deposits.

WORK ORDERS

Service Ticket 5801

Customer Complaint: Morning Dry Mouth and Irritated Sinuses

Equipment Type: Gas Furnace

A customer complains that the family wakes up in the morning with dry, cracked lips and irritated throat and sinus passages. They feel that the gas heat is to blame

and ask if another form of heat would cause less drying. The technician explains that the dryness is from heating the air, not from the type of heat used, and recommends installing a humidifier. The technician recommends an evaporative humidifier and installs it in the supply-air plenum. The customer calls back a week later thanking the company, saying that the parched morning conditions have disappeared.

Service Ticket 5802

Customer Complaint: Static Electricity

Equipment Type: Gas Furnace with a Plate-Type Humidifier

A customer has noticed that the amount of static electricity in her home seems high. She suspects that their humidifier is not working. The technician arrives and notices that the plates in the humidifier are hard and brittle, instead of soft. The technician explains to the customer that the plates are not very effective when they are calcified with mineral deposits. The humidifier is cleaned and the plates are replaced. The next day the static electricity in the house goes away.

UNIT 58—REVIEW QUESTIONS

1. What advantages are there to adding humidity to heated air?
2. What is the desirable amount of relative humidity that should be maintained?
3. What are the two general categories of humidifiers?
4. What types of humidifiers work well with heat pump systems?
5. Which types of humidifier require the least cleaning?
6. Why do most humidifiers require annual cleaning and media replacement?
7. Why should the humidity level in the house be reduced as the outdoor temperature drops?
8. Explain how a bypass humidifier works.
9. What are the two most common controlling elements in a mechanical humidistat?
10. How is steam humidifier operation different from evaporative humidifier operation?
11. Why should a steam humidifier be filled with water before it is energized?
12. How can an improperly maintained humidifier contribute to bad indoor air-quality issues?
13. Why do steam humidifiers require heavier electrical wiring than bypass-type humidifiers?
14. What is the purpose of the flush cycle used in some steam humidifiers?
15. On what types of heating systems can atomizing humidifiers be used?

UNIT 59

Electric Heat

OBJECTIVES

After completing this unit, you will be able to:

1. describe the different applications for electric heating.
2. explain the purpose of sequencers used for electric heating elements.
3. describe how the safety devices of electric furnaces operate.
4. determine the best application for supplemental electric heating.
5. explain the operation of a multistage thermostat for electric heating.

59.1 INTRODUCTION

The growth of electric heating began in the 1950s and first became popular in areas not served by natural gas pipelines. Throughout this same period, the electrical demand for air conditioning during the summer months was increasing. To help boost the winter demand, electric utilities and heating manufacturers began to encourage the use of electric heating. Special rates and promotional programs like “Live Better Electrically” and “Total Electric Home” were introduced in the 1960s, and the market developed rapidly.

Today, many systems provide both heating and cooling with a single air-distribution system. Therefore, most air handlers are configured to accept both cooling coils and heating elements. This has reduced the number of installations for straight stand-alone electric furnaces, and instead electric heat is often used in combination with a cooling system or heat pump.

59.2 WARM AIR ELECTRIC FURNACES

The typical residential electric furnace (Figure 59-1) consists of a cabinet, blower compartment, filter, and resistance heating section. Most manufacturers provide a place for a cooling coil. An electrical furnace has many advantages:

- It is more compact than the equivalent gas or oil furnace.
- Due to cooler surface temperature, it has “zero” clearance requirements on all sides. It may, therefore, be located in small spaces, such as closets.
- Since there is no combustion process, there are no requirements for venting pipes, chimney, or makeup air. This reduces building costs and simplifies installation.
- Units may be mounted for upflow, downflow, or horizontal airflow applications (Figure 59-2).

With electric heat there are no losses such as those experienced with oil and gas combustion processes. Therefore electric heat is considered to be close to 100 percent efficient.

Figure 59-1 External view of an electric furnace.

Figure 59-2 Various types of electric furnaces.

TECH TIP

Always try to help your customer understand the different cost alternatives available. Electric heat is almost always more expensive than other types. Think of electrical power to be a finished product as compared to a raw material. As an example, a sheet of plywood will cost more than rough sawn boards. In the same way, electrical power will cost more than gas or oil. Sometimes there are discounts offered by power companies. Often large users of electrical power can take advantage of lower rates and off-peak reductions.

The blower compartment is a housing that includes the filters and the blower fan for circulating the air through the system. Smaller units will use a centrifugal multispeed direct-drive fan while larger units use a belt-driven fan. An electric furnace has less resistance to airflow as compared to an oil or gas furnace, and fan performance is more efficient.

The heating section consists of banks of resistance heater coils of nickel chrome wire held in place by ceramic insulators (Figure 59-3). The heater normally operates on a 208 V to 240 V power source. The amount of heat produced by each heating element is affected by the supply voltage and the current flow, which together determine the total wattage.

One watt of power produces an equivalent 3.412 BTU/hr of resistance heat. Electric power is measured in kilowatts (kW), with 1 kW being equal to 1,000 W. The term kilowatt-hour (kWh) is used to express the amount of energy used in 1 hour. The input for an electric furnace is given in kWh and the output is given in BTU/hr (also referred to as BTUH, but either way, it is BTU per hour). To find the heat output in BTU/hr, multiply the kW input by 3,412. Conversely, the input kW can be calculated by dividing the furnace BTU/hr output by 3,412.

The amount of heat produced by an electric furnace is a function of the supply voltage and the current flow.

$$\text{Watts} = \text{Volts} \times \text{Amps}$$

A furnace rated at 240 V with a current draw of 125 A would have a kW input of $240 \text{ V} \times 125 \text{ A} = 30,000 \text{ W}$, which

Figure 59-3 Electric heating element rack.

is 30 kW. Residential furnace output capacities normally range from 5 kW (17,060 BTU/hr) to 30 kW (102,360 BTU/hr).

A 30 kW, 240 V electric furnace has a current draw of 125 A, which for a 200 A entrance panel would leave only 75 A for other electrical uses. If the total heating demand is greater than this, then two electric furnaces would be used, with sequencing and zoning.

SAFETY TIP

All electrical work **MUST** conform to the requirements of local codes and ordinances and the National Electrical Code NFPA 70, current edition.

59.3 SEQUENCERS

The sequencer control is an important operation of the electrical furnace. When there is a call for heat, the electric sequencer contacts close and the circuit is energized. As the sequencer begins to heat up, the blower and first heater come on. To stage the elements, there is a time delay (in seconds) before each additional heater stage is energized.

Electric furnaces that have multiple heat strips are designed with a sequencer that allows each heat strip to come on individually or in small groups. Most systems use sequencers to sequence or stage on elements. A sequencer uses a small heating element wrapped around a bimetal strip or a PTC control. When the bimetal strip warms up enough, it snaps or warps to close a set of contacts to turn a heat strip on. Some sequencers have multiple contacts that are staged on. Staging can be accomplished by using a center pin that pushes upward on each successive set of sequencer contacts (Figure 59-4). In some cases where several heating elements are sequenced to turn on, multiple sequencers are used (Figure 59-5).

To prevent the heating elements from overheating, the unit blower must come on with the first heating element and

Figure 59-4 White center pin shown pushes upward on contact.

Figure 59-5 Multiple sequencers.

it must remain on throughout the heating cycle until the last-stage heating element has cycled off. Some sequencers have specific terminals that are designated for the blower. This set of contacts is the first on and the last off in the sequence.

SERVICE TIP

UL requires that the blower come on with or before the first heat element and must remain on until the last heating element has been de-energized.

The time interval between when a sequencer is energized and when its contacts close is predetermined, within a range, by the sequencer's manufacturer. Some manufacturers offer sequencers with different time cycles. Likewise, the time interval between when a sequencer is de-energized and when each of the contacts drops out is preset by the manufacturer. In some cases, although the sequencers may come on one at a time sequentially, they may all go off at the same time together. Check with your supply house or the manufacturer to see what time cycle is required for the unit you are working on.

59.4 HEATING ELEMENTS

The heating elements used in electric furnaces are made out of a nickel chrome alloy. The nickel chrome alloy is used because it has both a high electrical resistance and slows down oxidation. Many metal alloys have an electrical resistance too low to be effective heating elements. Also, many alloys are susceptible to extreme oxidation at elevated temperatures. Heating elements appear to be long coil springs and are bright in color until the coil is heated. As the elements are used, they will begin to discolor. Eventually, they will become dull black in color. The length of the heating element determines its kW capacity. Heating elements are available in 5 kW through 30 kW capacities for residential electric furnaces and may be as large as 60 kW or more for commercial electric furnaces. The typical kW options of a heating unit are shown in Figure 59-6. Figure 59-7 shows the heating elements held in place by ceramic spacers.

Electric heating elements are rated by their kW capacity and come in a prewired rack. Each electric furnace is designed to hold a specific type and size of heating element rack. These racks are not interchangeable from manufacturer to manufacturer, or in many cases from one model furnace to

Figure 59-6 Nameplate for 60 kW commercial heater.

Figure 59-7 Heating element for 60 kW commercial heater.

Figure 59-8 Electric heating element restringing kit.

another within the same manufacturer’s product line. When replacing a heating element rack, be sure that you specify the model and serial number of the furnace the rack is to fit into.

Some heating element racks can be restringing with a replacement heating element (Figure 59-8). An advantage to restringing heating elements is that only a limited number of heating element sizes need to be stocked in your service van. However, replacing the heating element rack results in a significant time savings over restringing, and you are providing the customer with an entirely new part. Sometimes the ceramic insulators can be damaged during restringing, such as the one shown in Figure 59-9. A damaged insulator may fail sometime after the installation job is complete.

59.5 APPLICATIONS

One common application of an electric furnace is to combine it with a split-system heat pump. Whenever the outdoor temperature drops below the thermal balance point of the structure, the heat pump alone may not be able to maintain a comfortable indoor temperature. This is when the electric furnace will supply the additional heat necessary to maintain the thermostat setpoint.

Figure 59-9 Damaged ceramic insulator.

Figure 59-10 Split-system heat pump.

An example of an electric furnace and heat pump combination installation is shown in Figure 59-10. For these installations, the electric furnace acts as a fan coil unit. The refrigerated coil is installed in the furnace return-air stream before the blower. The coil is connected by refrigerant tubing to the outdoor heat pump located on a slab outside the building. The thermostat is located in the conditioned space and controls the operation of the complete system to produce the heating or cooling as required.

An advantage of using an electric furnace as a supplemental heat source in a heat pump application is that this creates a draw-through coil for the heat pump. This is the most efficient application for an indoor heat pump coil. This is in contrast to gas or oil supplemental heating systems, where the coil must be located after the firebox to prevent condensation from forming on the heat exchanger.

Because of energy conservation concerns, some cities, counties, and states have ordinances or laws that prevent straight stand-alone electric furnaces from being installed in new construction. This is because heat pumps are more efficient and under normal operating conditions will use less electricity. In those localities, heat pumps are used for primary heating in conjunction with electric furnaces that supply only supplemental heat.

59.6 ELECTRIC FURNACE CONTROLS

There are single-stage and two-stage thermostat systems, depending on the size of the unit. Figure 59-11 shows a thermostat that has a single stage for heating and a single stage for cooling. A fan control switch lever can be set to operate at low, medium, or high speed whenever the heating or cooling equipment cycles on.

Larger furnaces and some heat pumps use multistage thermostats. For electric furnaces, the first stage would

Figure 59-11 Single-stage heat/cool thermostat.

bring on at least 50 percent of the total capacity. The second stage of the thermostat would respond only when full heating capacity is needed. With this added control, wide variations in indoor temperature are avoided. For heat pumps, the first stage brings on the heat pump and the next stage brings on the electric strips as needed.

Figure 59-12 shows a thermostat with two-stage heating and cooling, and the system switch settings to control the thermostat operation are as follows:

- **OFF** Heating and cooling systems are off. If the fan switch is in the AUTO position, the cooling fan is also off.
- **COOL** Thermostat controls the cooling system. Heating system is off.
- **AUX. HEAT** Auxiliary heat is on. Cooling system is off.

Figure 59-12 Two-stage heat/cool thermostat.

- **HEAT PUMP** First-stage heat is on. Cooling system is off.
- **2 STG. HEAT** First- and second-stage heat is on. Cooling system is off.

Electronic or digital thermostats use thermistors or other integrated circuit devices to sense temperature changes. The system and fan selections can be operated by a keyboard (Figure 59-13). The installer setup is used to customize the thermostat to specific systems. The fan can be configured to be operated in the heat mode either by the equipment or by the thermostat. The heating cycle rate can be adjusted for stage-two heating. Fan operation can be extended to continue after the call for heating or cooling ends.

SERVICE TIP

While sequentially staged design features are feasible for modifying the load, code assumes all installations are used continuously, for safety purposes.

Figure 59-13 Programmable thermostat keyboard.

59.7 ELECTRIC FURNACE AIR DISTRIBUTION AND BLOWERS

Air-handling capabilities of electric furnaces are similar to other forced-air furnaces, using a multispeed direct-drive blower. Multispeed direct-drive blowers have the capability to adjust the blower speed to deliver the required air quantity depending on the static resistance of the supply- and return-air duct system.

The air-distribution system for an electric furnace requires the following special considerations:

- Air temperatures coming off the furnace are lower, as compared to gas and oil equipment. Temperatures of 120°F and below can create drafts if improperly introduced into conditioned space. Additional air diffusers are recommended.
- Duct loss through unconditioned spaces can be critical, so well-insulated ducts are a must to maintain comfort and reduce operating cost.

59.8 SAFETY DEVICES

All electric resistance heating circuits have one or more safety devices to protect the system from overheating and over-current. Electric heating elements are protected from any overheating that may be caused by fan failure or a blocked filter. High limit switches sense air temperature and open the electrical circuit when overheating occurs (Figure 59-14).

As a backup, some furnaces have fusible links that melt when the heating coil temperature goes too high due to over-current conditions. This opens and protects the circuit. A fusible link (Figure 59-15) is a small one-time-use device that is

Figure 59-14 Limit switch for electric heat elements.

Figure 59-15 Fusible link.

Figure 59-16 Overload protector.

wired in series with the heating element. Some manufacturers use fusible links that are mounted in ceramic. Others use fusible links that are spot welded to the heating element. Fusible links are made of an alloy that melts at a specific temperature, generally at about 300°F. The advantage of a fusible link is that the melting temperature of the alloy remains constant over time. This provides the maximum level of safety because the fusible link will open instantly anytime an overcurrent situation occurs. Because the opening function of fusible links is based on the melting temperature of an alloy, they are highly reliable overload protectors.

A high limit is another heat protector for electric heating elements (Figure 59-16). High limits sense temperature so that in a high-temperature situation the limit will open. High limits will automatically reset once the bimetal strip in the limit has cooled sufficiently.

Inline cartridge (BUSS) fuses (Figure 59-17) are used to protect individual heating elements, groups of heating

elements, or the entire furnace. Fast-acting fuses should be used instead of dual-element time-delay types. The metal clips that hold cartridge fuses in place have sufficient spring tension when they are new to prevent heating of the connection between the fuse and the fuse holder. However, over time these connections can become loose, resulting in resistance that will cause them to heat up and lose their spring tension. If these clips have become discolored—even the slightest amount—they should be replaced before the resistance gets high enough that an arc occurs between the fuse and fuse clip. To reduce damage to the fuse spring clips and work more safely, you should remove the fuses with a fuse-puller tool. Do not pry them out with a screwdriver.

SERVICE TIP

Some inexpensive cartridge fuses will deteriorate over time when used in an electric furnace. These fuses can actually burn through the outer casing when they fail. This can result in damage to nearby wiring. Use only quality fuses such as those purchased from air-conditioning and refrigeration supply houses. If a customer replaced fuses on their unit with lower-grade fuses, you should change them (or at least note it on your service ticket).

Circuit breakers (Figure 59-18) may be used as overcurrent protection. Circuit breakers used on the 208 V to 240 V systems have two breakers that are interlocked so that overcurrent in one leg causes both breakers to open, removing power from the load. Some furnaces use more than one set of breakers so that individual parts of the heating circuit can be protected separately. An advantage of circuit breakers is that they can be reset.

(a)

(b)

Figure 59-17 (a) Cartridge-type fuse; (b) fuses are held by metal clips and should be removed with a fuse-puller tool and not by a screwdriver to preserve the spring tension of the clips.

Figure 59-18 Dual circuit breaker.

SERVICE TIP

Built-in fusing or circuit breakers are provided by some manufacturers in compliance with the National Electric Code. This eliminates the need for external fuse boxes.

CAUTION

All replacement wiring used in an electric furnace must have a rating of 105°C (221°F) with an AWM-type appliance wire rating. This wire will stand a much higher environmental temperature, which can be experienced within an electric furnace cabinet.

59.9 AIRHANDLING UNITS AND DUCT HEATERS

A variation of the electric furnace is an air-handling unit with duct-type electric heaters. The air handler consists of a blower housed in an insulated cabinet with openings for connections to supply and return ducts. Electric resistance heaters are installed either in the primary supply trunk or in branch ducts leading from the main trunk to the rooms in the dwelling. When heaters are installed in branch runs, there is comfort flexibility by zone control; for example, room temperature can be individually controlled. This system has not been as popular as the complete furnace package, primarily because it complicates installation requirements and adds costs.

Duct heaters are made to fit standard-size ducts and are equipped with overheat protection devices. Electric duct heaters can also be used to supplement other types of ducted heating systems, to add heat in remote duct runs, or to beef up the system if the house has been enlarged. They may be connected to come on with the furnace blower and are thus controlled by a room thermostat. Additional safety may be achieved by installing a sail switch in the duct that must sense air movement before the duct heater will come on.

Figure 59-19 Installation of a slip-in-duct heater. (Brasch Mfg. Co., Inc.)

Slip-in-duct-type heaters are the most widely used because they are the easiest to install, as shown in Figure 59-19. A hole is cut into the duct and then the heater is secured with sheet-metal screws.

Another type of duct heater is the flanged type. The flanges on the heater match those of the duct and are screwed into place with sheet-metal screws, as shown in Figure 59-20. There are also heaters that can be installed into round ducts (Figure 59-21).

Multistep heaters use electronic modulation with solid-state electronic step controllers. Some of these can switch up to ten contactor-holding coils apiece and may be wired in series for a maximum of thirty steps. They are available with a single input from all commonly used thermostat input signals.

Figure 59-20 Installation of a flanged duct heater. (Brasch Mfg. Co., Inc.)

Figure 59-21 Round duct heater.

Figure 59-22 Modulating thermostat signal.

Silicone-controlled rectifiers can be used to provide very close heat control and/or silent operation for critical areas such as laboratories, computer rooms, and executive offices. Power and heat output are precisely controlled from 0 to 100 percent in direct response to the modulating thermostat signal (Figure 59-22). All the heating elements are simultaneously controlled.

59.10 ELECTRIC HYDRONIC BOILERS

Electric hydronic boilers heat water that is then circulated to the spaces to be heated rather than by blowing hot air through a duct system. This type of boiler can be used for standard baseboard radiant heaters or for under-floor radiant heat. Other applications include supplemental heat for oil, gas, and wood-fired systems.

Hydronic systems are popular in geographical locations where there is little need for air conditioning. Most heating/cooling systems will utilize the same air-distribution system that requires supply and return ducting throughout the residence. Without the need for air conditioning, this ducting is not necessary, and instead water circuits can be installed. Each circuit (zone) can be configured with its own circulation pump and temperature control. In-the-floor radiant heating has grown in popularity and provides for an even, prolonged heat once the entire floor has come up to temperature.

59.11 BASEBOARD HEATERS

Electric baseboard heaters can easily be installed in spaces where additional heating is required (Figure 59-23). Typically they can be wired for 120 V, 208 V, or 240 V applications, but 240 V is recommended. This type of heater operates on the principle of natural convection, and there is no fan or blower attached to it. The best location for an electric baseboard heater is along an outside wall, as close as possible

Figure 59-23 Electric baseboard heater.

to an outside door, or directly under a window, which takes advantage of the natural air currents: the cold air falls from the window area and the warm air rises.

SAFETY TIP

Do not block an electric baseboard heater. It must be kept clear of all obstructions with at least 12 in minimum clearance in front and above the heater with a 6 in minimum on each side. Do not place the heater against paperboard or low-density fiberboard surfaces. Do not install the heater behind doors or place the heater below an electrical receptacle.

Electric baseboard heaters come in many sizes, from as short as 2 ft in length up to 8 ft or more. They can range from as low as 250 W up to 2,500 W. Being quiet, they are ideally suited for bedrooms. A thermostat is required, and this may be of the type that is mounted on the wall or built in to the heater. When servicing a unit, check for any accumulation of lint or dust. This can be vacuumed away carefully, while taking care not to damage any of the aluminum fins on the heat exchanger.

A variation of an externally mounted electrical baseboard heater is a register type of electrical heater. This type of heater is more difficult to install but has the advantage of being mounted flush into the wall. They also come equipped with a fan to provide forced-air circulation, resulting in better heat transfer. However, due to the blower assembly, this type of heater is not as quiet as a standard baseboard type.

Register-type electrical heaters can also be configured for 120 V, 208 V, or 240 V, with 240 V normally recommended. They can range in output from 500 W up to 2,000 W. A hole will need to be cut into an existing wall for installation. After the wall can is secured, the heater assembly with the blower wheel is screwed into position (Figure 59-24). During installation, the manufacturer's recommendations for top, front, bottom, and side clearances should be followed. Thermostat and periodic cleaning requirements are similar to those for electric baseboard heaters.

Line-Voltage Thermostats

Most electrical baseboard-type heaters will utilize line-voltage thermostats. Typically these heating units do not have step-down transformers to supply 24 V to the thermostat. Instead,

Figure 59-24 Register electric heater blower assembly mounting.

Figure 59-25 Typical line-voltage thermostat.

the thermostats will be wired directly into the operating circuit and therefore at line voltage (Figure 59-25). All wiring must comply with local codes and be of sufficient size for the circuit requirements.

CAUTION

Line-voltage thermostats control 120–240 V circuits. If improperly handled, there can be risk of 120–240 V electric shock hazard that can cause serious injury or death.

UNIT 59—SUMMARY

Electric furnaces are somewhat compact, need only minimal clearance, and require no makeup air or exhaust vents. Although there are applications for electric heat stand-alone

systems, very commonly it is used as a supplemental form of heat. Although very efficient, electric heat can often cost more than comparable oil, gas, and heat pump systems. However, electric heat can be added to an existing room with only moderate modifications through the use of baseboard heaters, in-the-wall duct registers, and duct heaters.

When used with a heat pump, the electric heat turns on as outside temperatures drop below the normal heat pump operating range. This type of two-stage heating is common, and many thermostats are configured for these applications. Staging can also be controlled between heating elements, allowing them to turn on and off depending on the thermostat setting and the heating demand. It is always important to note that while sequentially staged design features are feasible for modifying the load, code assumes all installations are used continuously.

WORK ORDERS

Service Ticket 5901

Customer Complaint: Drafty Alcove

Equipment Type: 4-Foot Electric Baseboard Heater

The technician met with the customer in regard to upgrading an existing heating system. The complaint was that an alcove near the front entrance to the home was drafty. Although this area was used mostly as an entrance, the customer would sometimes work at a small desk located there and feel cold.

The technician inspected the existing system, which was gas-fired forced hot air. He explained to the customer that to supply heat to this space, new ductwork would need to be added and a hole for a register cut into the floor. Some additional calculations would also need to be considered to determine if the existing airflow and furnace size could accommodate the additional length of duct. In any event, this modification was not simple and could be expensive. The technician recommended an electric space heater that could be turned on whenever the customer worked at the desk. The customer did not like this idea because the space heater would always be in the way.

Agreeing with this, the technician recommended two other alternatives. One was an electric baseboard heater and the other was a register-type forced-air electric heater mounted into the wall. The customer decided on the register heater with a wall-mounted thermostat. The existing furnace would not need to be modified. The electric heater could be set to turn on through the thermostat setting whenever the customer desired heat.

Service Ticket 5902

Customer Complaint: Supplemental Heating

Equipment Type: Wood-Fired Furnace with Oil Backup

The customer set up an appointment to meet with a sales representative to discuss the alternatives available for supplemental heat. Originally the residence was

heated by hot water baseboard heat supplied from an oil furnace, but a new wood-fired boiler was installed 2 years ago. This was done to offset the high cost of heating as the price of firewood was very reasonable in this geographical area.

This new system worked very well, but the wood furnace needed to be tended on a regular basis. If the customer was home late from work or away for a few days, the oil furnace would come on and provide heat to prevent any freeze-up in the house. However, the existing oil furnace was now in need of replacement. The oil tank was also starting to develop leaks. A new oil furnace and tank would be a costly proposition. The sales representative discussed the possibilities for supplemental oil, gas, or electric heat. The customer decided on electrical heat because there was no convenient gas supply, and an added convenience of electric heat is that no fuel oil deliveries would need to be regularly scheduled.

Service Ticket 5903

Customer Complaint: Residence Too Cold

Equipment Type: Forced-Air Heat Pump

The technician first spoke with the customer and then checked the system and found everything to be operating correctly. Apparently from what the customer had explained, in the evening as the temperature dropped, the house would feel chilly. The customer also noticed that the room temperature would fall well below the thermostat setting.

The house was new and this was the first winter that the customer had spent there. During the summer months, the house temperature was very comfortable no matter how hot it became outside. The technician checked the owner's manual for the heat pump and found that its efficiency dropped when the outside air temperature fell below 40°F. There was no supplemental heating element installed in the existing system.

The technician recommended that supplemental electrical heating elements be installed into the air handler. The unit was adaptable for this add-on, so the existing system could be used. The single-stage thermostat

would need to be changed out and a programmable two-stage was recommended. Once the heating elements and the new thermostat were in place, the room temperature remained at the thermostat setpoint level even during the cool hours late into the evening.

UNIT 59—REVIEW QUESTIONS

1. List three advantages of a warm-air electric furnace as compared to an oil or gas furnace.
2. What material are electric heater coils often made from?
3. An electric furnace rated at 240 V and 30 A would have an output capacity of how many kilowatts?
4. What happens to the current draw as an electric heating element warms up?
5. When would the blower come on in an electric furnace?
6. Why is nickel chrome alloy used for electric furnace heating elements?
7. How are electric heating elements rated?
8. How would a multistage thermostat operate for a heat pump system with supplemental electric heat?
9. How do air temperatures compare between electric furnaces and those that are gas or oil fired?
10. What is the function of a high-limit switch on an electric heater?
11. What is a fusible link on an electric heater?
12. How does an overload protection device on an electric heater differ from a fusible link?
13. What happens when the spring clips holding an inline cartridge fuse become loose?
14. What are the requirements for replacement wiring in an electric furnace?
15. What is a term used for a furnace that heats hot water that is then circulated for space heating by a circulation pump?
16. What is an advantage of an electric baseboard heater?
17. In what locations should electric baseboard heaters be installed?

20. Why are hydronic furnaces popular in geographical areas that do not require air conditioning?

UNIT 60

Electric Heat Installation

OBJECTIVES

After completing this unit, you will be able to:

1. list the installation methods used to support an electric furnace.
2. discuss sizing of the power wire, overcurrent protection, and disconnect.
3. discuss the effect of reduced voltage on furnace capacity.
4. list the operational checks for a new electric furnace installation.

60.1 INTRODUCTION

Electric heat installation is less complicated to install than most other types of heating. The only connections required are the electrical wiring, the thermostat controls, and the air ducting. This makes electric heating very desirable for many multifamily residential, light commercial, and commercial applications, especially when only limited heating is required.

This limited heating is typical in areas where the cooling load is predominant. Therefore it is very common to find electric heat used in tandem with cooling units. Unlike a stand-alone electric furnace, most air handlers can be adapted for both electric heating elements and cooling coils. In this way, the same air-distribution system can be used for both the heating and cooling modes. The installation of a heating/cooling air handler is more involved than a stand-alone electric furnace partly due to the cooling coil refrigerant connections. However, the basic location, support, and duct connections for an air handler as compared to a stand-alone electric furnace can be very similar.

60.2 WARM-AIR ELECTRIC FURNACE INSTALLATION

The installation of a warm-air electric furnace requires a few preliminary considerations. The furnace should be located in an area that will provide for proper clearance from combustible materials and also allow for good support. The plenum connection should be adjusted to fit properly and sealed to prevent air leakage.

Furnace Location

An electric furnace's installation is flexible; it may be installed almost anywhere in a building. Electric furnaces do not need a vent, so they can be located in places where fossil fuel furnaces, such as those burning gas or heating oil, cannot be located. Electric furnaces also weigh much less than fossil fuel furnaces, so they are easier to support or hang. Most electric furnaces are multipositional, so the same furnace may be installed in the upflow, downflow, or horizontal position without modifying the unit. While multipositional fossil fuel furnaces are available, they typically

require the removal and relocation of several parts to change from one position to another.

Furnace Support

In slab on-grade and basement installations, the furnace would typically rest on a return-air box called a plenum. Return-air boxes may be made out of sheet metal or duct board or framed in with standard building materials. A sheet-metal return-air box is shown in Figure 60-1. The

Figure 60-1 Sheet-metal return-air box.

Figure 60-2 Upflow electric furnace installation.

electric furnace would be positioned to sit on top of the return-air box, which houses the filters (Figure 60-2).

In crawlspace installations, the furnace is suspended from the floor joists; in attic installations, it can be suspended from the roof rafters.

Because the fan noise and vibration will be transmitted to the ceiling through the joists in attic installations, the furnace should not rest directly on the ceiling joists or on plywood on top of the ceiling joists. The ceiling acts like a soundboard and amplifies the sound of the furnace. An air handler located in an attic and resting on vibration isolation pads is shown in Figure 60-3.

Furnace Clearance

Always refer to the manufacturer's literature and appropriate local codes to determine the furnace clearances. The *furnace clearance minimums* are the minimum distances from

Figure 60-4 Minimum clearances for a closet installation.

each of the furnace surfaces to any combustible materials. The manufacturer's literature and/or local codes will provide these distances. An example of a furnace installed in a closet is shown in Figure 60-4. Not all of the furnaces' surfaces will require the same minimum clearances. The bottom of the furnace may rest directly on a plywood base with 0 in clearance, but the front may require 24 in or more for service. However, ideally, the service clearance should be at least 36 in.

Plenum Connections

There is a $\frac{3}{4}$ -in flange on the furnace supply-air and return-air outlets. To protect the $\frac{3}{4}$ -in furnace supply-air plenum flange from damage during shipping and handling, some manufacturers leave the flange flat. On these furnaces, the technician will have to bend the flange 90° outward so it can be used to attach the supply-air plenum.

Care should be taken when bending the flange outward not to distort it excessively. To avoid excessive distortion, do not bend the flange 90° all at once. It is important that you bend the tab up as uniformly as possible so that the top edge does not stretch and warp excessively. To minimize distortion, make a series of smaller angled bends along the length of the flange. Start at one end, and bend it slightly upward. Move along the flange, and repeat that slight bend. Start over again, and make another slight bend. Repeat this process until the desired 90° bend is completed.

Figure 60-3 Air handler resting on vibration isolation pads.

Figure 60-5 Duct connector.

TECH TIP

The best tool to use for bending the supply-air flange are hand seamers, sometimes called hand brakes.

If the furnace is being installed in the vertical up position, the furnace flange does not need to be bent up. The furnace can be secured directly to the plywood base with sheet-metal screws. Be sure to seal the connection between the base and furnace with duct mastic and fiberduct tape.

The duct connections will vary between furnace types as to whether they may be upflow, downflow, or horizontal configurations. Figure 60-5 shows a reducer for connecting the furnace to the duct in an under-the-floor supply duct system for a downflow furnace. A duct opening would need to be cut out in the floor as shown in Figure 60-6. The connector tabs will need to be bent over to fasten the connector to the duct, as shown in Figure 60-7. Depending on the air-supply and return system, a rectangular-to-round connector

Figure 60-6 Duct cutout.

Figure 60-7 Bending tabs on connector.

Figure 60-8 Rectangular-to-round duct connection.

may be required for flex duct, as shown in Figure 60-8. If flex duct is used, it must have a minimum temperature rating of 200°F and meet all other applicable codes and standards.

An over-the-floor return-air system for an upflow furnace is shown in Figure 60-9. In this installation, the furnace is mounted slightly above the floor and the return-air register is mounted in the wall. For an upflow or horizontal furnace, a sheet-metal plenum can be attached directly to the furnace flange with sheet-metal screws. Fiberduct board should not be connected directly to these flanges. If duct board or other

Figure 60-9 Over-the-floor return-air system.

similar materials are to be used, a 3-in-wide sheet-metal band must be attached to the furnace flange first. The metal collar is attached to the flanges with sheet-metal screws, and the fiberduct is connected to the collar using long sheet-metal screws with 2½-in-square large washers under the heads.

Plenum Sealing

To prevent air leaks, the supply and return plenums must be sealed with mastic. Mastic may be applied directly to sheet-metal plenums. Be careful when applying mastic. The sheet-metal edges may be sharp or have burrs. Fiber tape must be used when duct board or other such materials are used as plenums. Air leakage can also occur in the space in which the furnace is installed if it is not mounted and sealed properly.

60.3 SYSTEM SELECTION

A furnace should be chosen with a heating capacity at least equal to the heat loss of the room, area, or building being heated. The heat strips used in most electric furnaces are rated at approximately 5 kw per strip when operated on 240 V. Since each kilowatt produces 3,410 BTU/hr, the heat output of each strip is 17,050 BTU/hr. Therefore, electric furnaces typically are available in multiples of 17,000 BTU/hr.

The electric service capacity must be considered when selecting electric heat, because all forms of electric heat use large amounts of current. A 20 kw electric furnace will use approximately 84 A. A typical modern residential electric service connection is 150–200 A, while older houses have service connections of 60–100 A. In some cases, the home's electric service connection may have to be upgraded before an electric furnace can be installed.

The actual voltage the furnace will be operating on is also important. Although most electric furnaces will operate at voltages less than 240 V, there is a significant loss of heating capacity when the furnaces are installed on lower-voltage supplies. Table 60-1 compares the output and operating characteristics of furnaces operating on 240 V and 208 V.

60.4 ELECTRICAL WIRING

Power Wiring

The most important part of an electric furnace installation is sizing the power wiring. Due to the fact that electric furnaces

Figure 60-10 Warning label requiring use of copper conductors.

use large amounts of current, the power wiring is critical. The conductor should be sized using the wire-sizing tables of the National Electrical Code to handle the minimum circuit amperage rating listed on the unit data plate. In some cases the data plate lists data for several units. As an example, a furnace model identification number could vary from 10 kW to 23 kW. Generally the only difference is the number of strip heaters in the furnace. The installer must determine which data matches the actual furnace being installed and mark it on the data plate.

Sometimes aluminum conductors are used to save on installation cost, because large-gauge copper wire can be expensive. Before aluminum wiring can be considered for use, check the furnace manufacturer's warning label. Figure 60-10 shows a manufacturer's installation guide that prohibits the use of aluminum wiring. If no such guidance is provided, the installer must check to see if the connections on the furnace are designed for aluminum conductors. Typically, they will be marked "Cu/Al" if both copper and aluminum wire types are acceptable. If only copper conductors can be used, the lugs will be marked "Cu only."

Aluminum conductors require application of antioxidant paste to prevent a poor connection, which will result in oxidation.

TABLE 60-1 Electric Furnace Specifications

Strips	Kilowatts		BTU		Amps	
	240 V	208 V	240 V	208 V	240 V	208 V
1	5	3.7	17,050	12,786	20.8	18
2	10	7.5	34,100	25,534	41.7	36
3	15	11.2	51,150	38,301	62.5	54
4	20	15	68,200	51,068	83.3	72

CAUTION

It is dangerous to use improperly sized wire or the wrong type of wire on an electric furnace. This is true with any equipment, but it is even more of a concern with equipment that has a high current draw. The wire and wire connections may become hot if the wire is undersized or not compatible with the furnace connectors. This can cause fires in extreme cases.

The Overcurrent Protection and Disconnect

The furnace should be protected with a circuit breaker no larger than the maximum overcurrent rating on the data plate. In some cases the technician will have to determine which data to use. There should be a disconnect switch located within sight of the furnace sized at 115 percent of the unit’s minimum circuit ampacity.

Control Wiring

The control wiring should be done with 18-gauge solid copper wire. Typical mechanical-heating-only thermostats will have just two connections: one connection for the 24 V furnace transformer and another connection for the furnace controls (Figure 60-11).

With only two wires, it really does not matter which of the control terminals the wires are connected to. Some

Figure 60-11 Two-wire thermostat connection.

TABLE 60-2 Electric Furnace Control Wiring

Furnace Terminal	Wire Color	Thermostat Terminal	Purpose of Wire
R	Red	R	24 V power
W	White	W	Heat signal
G	Green	G	Fan signal
C	Any color	C	Common side of transformer
		Only used for digital thermostats	

systems may have a third wire to control the fan. With three wires, the connections do matter. Some digital thermostats also require a common wire from the transformer to operate the thermostat. Table 60-2 shows typical control wiring connections between the thermostat and the electric furnace.

Some electric furnaces require a thermostat that is designed for electric heat because the thermostat controls the fan operation in the heating mode. These systems would require three control wires.

TECH TIP

Some thermostats have a jumper that configures the thermostat for either gas or electric furnaces. On the gas position, the thermostat does not send 24 V to the G terminal on a call for heat, so the furnace controls must energize the fan. On the electric position, the thermostat does send 24 V to the G terminal on a call for heat, energizing the fan.

60.5 START-UP PROCEDURES

Newly installed equipment should always be started to verify that everything is operating properly. This begins with a prestart inspection followed by an operational check once the equipment is running.

Prestart Inspection

The incoming voltage should be checked and compared to the data plate rating. Perform a visual inspection on all wires and wire connections. Loose connections will cause overheating and degradation of wires, wire lugs, and fuse blocks. If aluminum power wire is used, make sure the furnace connections are rated for aluminum conductors and antioxidation paste is used on the connections.

Operational Check

Checking the power source and all electrical connections is essential when starting an electric furnace for the first time. Because electric furnaces use large amounts of power,

any resistance in any of the power-handling components causes a voltage drop and leads to heat and failure of that component.

The voltage to the furnace should be checked before and after starting the furnace. A voltage drop indicates a problem with the power wiring to the furnace. The voltage at the heating elements should be checked and compared to the voltage entering the furnace; they should be the same. If they are not, then there is a problem in the furnace.

A furnace problem can be located by measuring the voltage across all the power-handling components. An infrared thermometer can also help. The point of voltage drop will be hotter than the rest of the wires and components. The current draw of each heating element should be checked and compared to the data plate rating. After all heating elements are operating, measure the temperature of the air entering and leaving the furnace. The difference between these two temperatures is the temperature rise. The temperature rise should fall within the range listed in the furnace installation instructions. If the temperature rise is too high, the fan speed should be increased. If the temperature rise is too low, the fan speed should be decreased.

UNIT 60—SUMMARY

A successful installation starts with proper selection, careful planning, and attention to detail. Equipment should be sized to meet the building's heat loss, the building's electrical service must be adequate, and the equipment should be located where it may be easily serviced. Sizing and selection of the power wire, the overcurrent protection, and the disconnect are all vital for the safe and efficient operation of the furnace. Finally, the furnace operation should be checked to verify that it is operating within manufacturer's specifications.

WORK ORDERS

Service Ticket 6001

Customer Complaint: Poor Heating on Cold Days

Equipment Type: 15 kw Electric Furnace

A technician is called to check an electric furnace that was installed several years ago. The customer complains that the furnace will no longer keep the house warm on cold days.

The technician visually checks the furnace and sees no obvious problems. The furnace is started and the voltage and amperage are checked to each of the heating elements. A reading of 240 V is found to be supplied to each of the heating elements except one that shows no current draw. After turning the furnace off, the technician shuts off the main power supply and locks out the circuit as a safety precaution. The circuit is also checked to verify that there is no voltage before the technician

(a)

(b)

Figure 60-12 Restringing a broken heating element.

begins disconnecting the power leads from the troublesome heating element. An ohmmeter measurement of infinity indicates that the element is open, and a visible break can be seen in the heating element.

The broken element is removed and a new element is restrung (Figure 60-12). After the heating element is replaced and reconnected, the power is turned on and all of the elements are rechecked. A heat rise test is performed, and the furnace is found to be operating correctly according to the manufacturer's data plate.

Service Ticket 6002

Customer Complaint: Poor Heating on Very Cold Mornings

Equipment Type: 10 kW Electric Furnace

A technician is called to check an electric furnace that was recently installed. The customer complains that the heating capacity of the furnace seems inadequate on very cold mornings. The technician is also informed that a load study was performed by the local utility company

just a few months back. This energy audit was part of a campaign to help homeowners find potential energy losses and hopefully lower their electricity costs.

In this instance the load study resulted in a design heat loss of 34,000 BTU/hr. The technician checked the furnace rating and found that it matched the design load with an operating voltage of 240 V. Checking the voltage to the furnace, the technician measured only 210 V before the heating elements were energized and only 208 V when the elements were on. Other than the low voltage supply, there seemed to be no other problems with the operation of the furnace. The technician explained to the customer that the furnace is rated for 240 V and that the heating capacity will be reduced when operating at a lower voltage.

Service Ticket 6003

Customer Complaint: No Fan on Auto

Equipment Type: 15 kW Electric Furnace

A technician is called to look at a newly installed electric furnace whose fan does not seem to be operating properly. The customer explains that whenever the fan switch is set to auto, the furnace does not seem to work. The technician then tries to start the furnace with the thermostat set in this position and finds that the heating elements are energizing and then cycling on overload because the indoor fan does not come on.

The technician then changes the thermostat fan switch setting to ON. In this instance, the fan operates normally and the furnace heating elements remain energized. The technician notes that the thermostat is the type that can be configured for both electric and gas furnaces, and it is found that the fan jumper in the thermostat is set to "gas." The technician moves the jumper to the electric position and now the fan comes on whenever there is a call for heat.

Service Ticket 6004

Customer Complaint: Air Temperature Too Low

Equipment Type: 10 kW Electric Furnace

A technician is called to check a newly installed electric furnace. The customer complains that the air being supplied to the room is not hot enough. The first check that the technician makes is to measure the furnace temperature rise. This is found to be only 30°F. The technician reviews the furnace operating instructions and finds that the recommended temperature rise is listed at 40°F.

Next the technician measures the furnace and heating element voltages. This seems to check out as it

should, with 240 V coming into the unit and 240 V measured at the heat elements. A current measurement provides an amperage reading of 20 A on each of the two heat elements. The furnace seems to be operating properly, so the technician checks the blower and finds that it is set to the highest speed tap. The technician moves the blower speed to low, starts the furnace, and then performs another check on the temperature rise. Now the temperature rise is 40°F and the supply air feels noticeably warmer to the customer.

UNIT 60—REVIEW QUESTIONS

1. Why should furnaces not rest directly on the ceiling joists?
2. How is fiberduct connected to the furnace?
3. How is the power wire sized for an electric furnace?
4. What is necessary to make a safe connection with aluminum wire?
5. An electric furnace has a minimum circuit ampacity rating of 50 A. What is the minimum current rating for the disconnect switch?
6. Where should the disconnect switch for the furnace be located?
7. How is the overcurrent protection sized for an electric furnace?
8. Discuss the effect of reduced voltage on electric furnace capacity.
9. Discuss the operational checks that should be made on a new electric furnace installation.
10. Draw a connection diagram for the 24 V controls on an electric furnace.
11. Why are all aspects of the power wiring circuit so important when installing electric furnaces?
12. Why should the electrical service to the house be checked before installing an electric furnace in an older house?
13. What can be done to remedy a furnace whose temperature rise is too high?
14. What is the most common size for heat strips in an electric furnace?
15. What is the current draw of the heat strips on a 15 kW electric furnace operating on 240 V?
16. List the installation methods used to support an electric furnace.
17. Is an electric furnace installation simpler than that for a gas furnace?
18. How are furnace clearances determined?
19. What is the best tool to use for bending a furnace air-supply flange?
20. Can mastic be used for duct board that will be used as plenums?

UNIT 61

Troubleshooting Electric Heat

OBJECTIVES

After completing this unit, you will be able to:

1. check electric furnace heating elements.
2. check electric furnace sequencers.
3. check electric furnace safety controls.
4. check the control circuit on an electric furnace.
5. measure the airflow of an electric furnace.

61.1 INTRODUCTION

Electric furnaces are the simplest form of warm-air furnace being sold today. However, they do still require service. Understanding how to properly check all the furnace components will save the technician time and frustration.

Service technicians must develop an understanding of the high-current circuit behavior to service electric furnaces. Due to the high current required for electric furnaces, even a minor connection resistance can lead to problems. Patience is also required because the controls are normally time delayed, and multiple time delay relays are common.

61.2 HEATING ELEMENT SERVICE

From time to time the heating element in an electric furnace must be replaced because it breaks. The most common cause of heating element failure is poor airflow. Reduced airflow causes increased temperature in the heating element, leading to failure. When a heating element breaks (Figure 61-1), it cannot be repaired and must be replaced.

There are several ways to identify a broken heating element: by amp draw, ohm readings, or by visual inspection. Visual inspection is usually not practical in the field

Figure 61-1 Broken heating element.

because the strips are not visible on an installed unit. The strips have to be removed to see them. The most commonly used method is to check the amperage draw of the heater elements.

Checking Heater Element Amperage Draw

When identifying a broken heating element by measuring the amperage draw, first turn on the system and allow time for all of the sequencers to energize. Next, use a clamp-on ammeter to carefully check each of the circuit's power wires for amperage and voltage (Figure 61-2). If an

Figure 61-2 Clamp-on ammeter used to measure amp draw.

element has a measured voltage but no amperage draw, then it is open.

CAUTION

Some newer digital multimeters have internal protection to prevent damage if a live circuit is touched when set to measure the resistance in ohms. However, not all meters have this protection, and accidentally touching your ohmmeter to a live circuit may blow an internal fuse or destroy the meter. If your meter does not have automatic protection as described in the owner's manual, you should check the circuit for voltage before switching the meter to measure resistance in ohms. This will help you prevent meter damage.

Checking Heater Element Resistance

The power to the furnace must be turned off before performing a resistance check of the heating elements. When using an ohmmeter to check for broken heating elements, first isolate the heating element to be measured. This is done by removing one of the power leads to the element. It is not necessary to remove both to isolate the circuit. Using your ohmmeter probes, check for continuity through each of the heating elements one at a time. A good element will have a measurable resistance reading that is fairly low, as shown in Figure 61-3a. A broken heating element will have an infinite resistance, shown as OL (overload) in Figure 61-3b.

Visual Heater Element Inspection

The heating elements must be removed from the furnace to conduct a visual inspection. Most furnace heating element racks can be removed once the power wires have been disconnected. Before disconnecting the wiring, make a sketch of the wire location so that you can easily reconnect them once the heating element racks have been replaced. There are typically two, four, or six sheet-metal screws that hold the rack in place. Once the rack is out, it can be inspected for broken insulators, broken heating elements, or any other visible damage.

When reinstalling the heating element rack, you must make certain that the alignment pin or bracket on the heating element rack fits into the slot at the back of the furnace. In most cases, the opening at the back of the furnace is slightly indented so that the alignment pin will track into the center opening. If the pin is not seated properly, the heating element rack will not slide completely into place or it may align at a slight angle. If this happens, do not force the rack into place with the screws. You must reposition it until it fits properly into place. Figure 61-4 shows an electric heating element rack.

Use both the manufacturer's wiring diagram and your own disassembly sketch as guides when reconnecting the wiring. In some cases, components may have been changed in older furnaces so that the manufacturer's diagram is no longer exactly correct. Therefore, you may need to rely mainly on your sketch when reconnecting the furnace wiring.

(a)

(b)

Figure 61-3 Using an ohmmeter to check heating element continuity: (a) a reasonable value of ohms indicates a working element; (b) a reading of ∞ or OL for overload indicates a broken element that must be replaced.

Figure 61-4 Electric heating element rack. (Courtesy of HVAC Department, Terra Community College, Fremont, Ohio)

Figure 61-5 Electric heating element restringing kit.

Replacement heating elements are available either prestrung in a replacement rack or as individual elements that must be restrung by the technician (Figure 61-5). Make certain that the replacement heating element has the exact same kilowatt capacity as the one you are replacing. If a larger element is used, you might exceed the amperage capacity of the main power circuit. If a lower-capacity element is used, the furnace may not produce sufficient heat to keep the residence warm.

61.3 FUSIBLE LINKS

Fusible links are intended to protect the heating element from overheating. They are designed to open before the heating element burns apart. The most common cause for fusible links to open is poor airflow. If a furnace has one or more fusible links open, the airflow needs to be checked.

Fusible links are replaceable only if they are a separate component in the furnace heating circuit. Some fusible links are welded to the end of the heating element and are therefore not replaceable. Most replaceable fusible links are mounted on ceramic bases that attach in the sheet-metal heating-element rack plate (Figure 61-6). Make certain that you order a replacement fusible link that is specifically designed for your particular furnace. There are a number of different designs, and all are not interchangeable.

TECH TIP

Ceramic insulators are brittle, so be sure that you do not force them as you are inserting them into their fitted location on the furnace heating rack. Do not attempt to hold a ceramic fitting down into place with the fastening screws because this will most often result in a cracked insulator. If the insulator is cracked during installation, the part must be replaced. Figure 61-7 shows a cracked ceramic insulator. It is not safe or acceptable to use damaged ceramic insulators.

(a)

(b)

Figure 61-6 Fusible links: (a) installed in ceramic bases; (b) replacement for fusible link.

61.4 SEQUENCERS

All of the heating elements are not energized at the same time to avoid a large initial current draw at startup. The job of the sequencer is to turn on the heating elements in a specific order, or sequence. There is a wide variety

Figure 61-7 Broken ceramic insulator.

of sequencers used in electric heating systems. It is important to use a matched sequencer when making a repair or replacement. Two general types of sequencers are commonly used: individual time-delay relays and all-in-one controls.

Individual time-delay relays usually have one or two sets of contacts. A common application is for each control to energize a single heating element and also the next sequencer in line. That energized sequencer will likewise energize one element and the next sequencer in line. This pattern continues until all the elements are energized. Furnaces using this type of control system stage the strips on and off in that same order. The first set energized is also the first set shut off, and the last set energized is also the last set shut off. Figure 61-8 shows a typical time-delay relay type of sequencer.

Figure 61-8 Sequencer.

Figure 61-9 M terminal on a sequencer.

The all-in-one sequencers have a sufficient number of contacts to control all the heating elements and the fan. These sequencers have terminals specifically designed for the blower (Figure 61-9). The fan terminals should not be used for electric elements because their current rating is much lower than the rating designed for the heating elements. Unlike the individual time-delay relays, the all-in-one sequencers de-energize the strips in the reverse order that they are turned on. The first strip on is also the last strip off.

A sequencer can be checked before it is installed in the furnace by energizing the relay's sequencer heater terminals with the correct voltage and testing each set of relay contacts for continuity as they snap on. The relay sequencer heater voltage can be 24 V, 120 V, or 240 V, which can be very different from the voltage requirement of the heating element at the relay contact. Check the relay sequencer heater voltage carefully; applying an incorrect voltage to the relay sequencer heater can destroy it. You should also test the sequencer as it is de-energized to see that each of the contacts opens as it should.

Testing a sequencer is similar to testing a relay or contactor, except with a time delay. First check to see that the relay sequencer heater has the correct voltage. Once the relay sequencer heater is energized, a timing period will start. After a time delay of 30 seconds to 2 minutes, the relay contacts should close. The closing of the contacts can be detected by measuring the amperage draw to the heater. The measured voltage drop across the contacts after they close should be zero. A measurable voltage drop across the closed contacts indicates pitting, and the sequencer should be replaced.

When replacing a sequencer, cycle the furnace on and off several times to make sure that all the heating elements and the blower are switching on and off in the correct time cycle. The blower should be operating anytime one of the heating elements is energized.

TECH TIP

The contacts inside a sequencer cannot be visually inspected for wear. However, with an ohmmeter set to the $R \times 1$ scale and the relay energized so that the contacts are made, you can test for resistance between the contact terminals. The resistance of a good set of closed contacts should be between 0 and 0.1Ω . A slightly higher resistance means that the contacts are worn, while a high ohm reading indicates that the contacts are extremely pitted. In either case, the contacts must be replaced. An infinite reading means they are still open and should be replaced.

61.5 OVERLOAD

The limits in an electric furnace sense temperature. They are wired in series with the strips and open when the strips overheat. Limit problems can usually be traced to airflow problems. Low airflow will cause the strips to overheat, tripping the limits. If limits are tripping, the air filter and airflow need to be checked.

The high-limit switch (Figure 61-10) is not easily tested because it is auto-resetting. The service technician has to catch it when it opens. A voltage drop will be read across the overload if it has opened.

Another way of testing limits in an electric furnace is to use your clamp-on ammeter at the main power feed to the unit. Allow the unit to run for 15 to 20 minutes as you perform other checks. If any of the limits are opening, the total current draw to the unit will drop. Some digital ammeters have data-recording capacity so that the high and low amp readings remain in the instrument. These readings can be reviewed at the end of the test. This type of meter makes a limit test much easier.

Figure 61-10 Overload protector.

Figure 61-11 Tattle Tale for testing overload protectors.

A way of checking limits without being present is to place an electronic Tattle Tale (Figure 61-11) across the limit. If the limit opens while the heating element is energized, the Tattle Tale will indicate that the limit opened. After the heating element cools, the limit will close; however, the Tattle Tale will continue to indicate that the limit has opened.

Since the limits are auto-resetting, a problem that causes a limit to trip will often cause the limit to open and close repeatedly before it is noticed. This repeated opening and closing with a high current draw on the circuit will eventually take its toll on the limit and it will stay open permanently. This is easily tested by checking the voltage drop across the limit or by turning off the power and measuring the resistance of the limit. If it is open, the reading will be infinite.

Any limit problem should prompt the technician to check for airflow problems because airflow issues are usually the root cause of limit problems on electric furnaces.

61.6 WIRES AND TERMINALS

Electric furnace terminals carry large amperage loads. Any unusual resistance, such as that resulting from a loose slip-on connector at the terminals, will cause the terminal to discolor. A set of contacts in a relay or a sequencer that are pitted will heat up, and that heat will be transmitted to the slip-on connectors and connecting wire. If the resistance

Figure 61-12 Overheating causes the terminal to discolor and could cause wire insulation to melt.

is significant enough, heat can be generated to both discolor the terminal and melt the wire insulation, as shown in Figure 61-12.

SAFETY TIP

Any wiring used in an area subject to high temperatures must have an appliance rating. These wires will have labels stating that they are suitable for internal wiring of appliances where the wire may be exposed to temperatures not to exceed 105°F, as shown in Figure 61-13. Any other nonapproved wiring insulation may melt. This nonapproved wire can cause a short if used inside an electric furnace.

It is not recommended that you simply replace the terminal end if a wire and terminal have become overheated. The overheated copper conductor will have oxidized some distance back inside of the insulation. Merely cutting off the end, even if you remove several inches, will not prevent this

Figure 61-13 High-temperature wire for appliance use.

wire from overheating again. You must replace the entire wire with another wire of the same or larger gauge that has the proper AMW appliance rating. Any wires that are not properly rated will present a safety hazard.

If the slip-on terminal on a relay, sequencer, fuse block, or other component has become discolored as a result of overheating, that component should be replaced. It is not recommended to simply sand or buff off the terminal's oxidation. Terminals have a thin coating of highly conductive material that resists oxidation layered over a base of less resistant copper, steel, or brass. When the terminal is sanded, the outer coating is abraded away, exposing the sub-base material. These base metals are not as resistant to oxidation or as efficient as conductors when compared to the highly conductive surface coating material. Cleaning these terminals will only serve as a temporary fix and not a permanent repair because oxidation will occur more rapidly once the sub-base material is exposed.

TECH TIP

It is important that you use a quality crimping tool anytime you are putting a new end on a wire that is going to be used in an electric furnace. Furnaces have fairly large amperage draws, and if the terminal is not extremely tight, the slightest resistance can cause the terminal and wire to overheat.

61.7 BLOWER MOTOR

The blower motor used on an electric furnace is typically a multispeed PSC electric motor. The variable-speed operation allows the installing technician to match the system blower to the duct system the unit is to be installed on.

Some new blower motors do not have oil ports. These motors are supplied with a "lifetime" of lubrication sealed in the motor bushings. If one of these sealed motors has developed a bearing problem, it cannot be lubricated and must be replaced. Motors that have oil ports should be

Figure 61-14 (a) Zip oiler; (b) telescoping spout.

lubricated no more than once annually for heating furnaces and no more than twice annually for heating/cooling furnaces. The oil used to lubricate a blower motor must be specifically labeled as electric motor lubrication oil. Figure 61-14 shows oil that is commonly used to lubricate electric motor bearings. General purpose or penetrating lubricants like Three in One and WD40 are not acceptable. Some of these oils have detergents or solvents that will actually damage the motor's bearings over time.

Do not overlubricate blower motors, and follow any manufacturer's instructions (Figure 61-15). Most motors require just a few drops of lubricant in the oil fill ports located on each end. Excessive lubrication will result in oil running out of the bearing seals, where it will deposit on the inside of the motor housing and windings as a thin film. The dust present in an air handler will collect as a layer on this oil film, which then acts as an insulator and restricts airflow. In both cases, the motor will run hotter and the motor winding insulation will begin to break down. Over a relatively short period of time, this can cause the motor windings to short out.

If the motor has to be removed to lubricate the inner bearing, make certain that it is reinstalled with the oil fill ports facing up. Always make certain that the oil fill port plugs have been replaced before the motor is put back in service. Failing to cap these ports will allow dirt and dust

Figure 61-15 Oiling instructions on motor cover.

to collect, which will be carried into the bearing the next time the motor is lubricated. This can cause damage to the motor bearings.

61.8 FURNACE EFFICIENCY AND CFM

Compared to most furnaces, it is easier to accurately determine the exact airflow through the air handler of an electric furnace. It is fairly simple to set the fan speed properly to provide the 400 CFM of airflow per ton that is recommended for most air-conditioner air handlers. To calculate the actual CFM of an air handler, you must take the following readings:

- Total amperage draw of the heating elements. This amperage must be of the heating elements only; it should not include the blower.
- Voltage at the heating elements as the unit is operating.
- The return-air temperature.
- The supply-air temperature. Make certain that this temperature is not taken with a probe inserted in the supply plenum so that it would be in a direct line of sight with the heating elements. The radiant heat that the elements produce would give a false high reading.

Use the following formula:

$$\text{CFM} = \frac{V \times A \times 3.412}{\Delta T \times 1.08}$$

EXAMPLE 61-1: SOLVING FOR ACTUAL AIR FLOW IN CFM

A unit with the following operating characteristics:

Voltage at strips	220 V
Amp draw of strips	27.8 A
Return-air temperature	70°F
Supply-air temperature	117°F
Temperature difference	= 117°F – 70°F = 47°F

$$\text{CFM} = \frac{220 \times 27.8 \times 3.412}{47 \times 1.08} = \frac{20,868}{50.76} = 411 \text{ CFM}$$

Figure 61-16 Control voltage transformer.

61.9 TRANSFORMER

The transformer (Figure 61-16) in an electric furnace is subject to a greater load than most HVAC transformers because the system may have a number of sequencers, all of which have heat motors that use 24 V. It is important to check the secondary voltage supplied by a control voltage transformer while the system is operating to determine if the transformer can supply 24 V under load. When a transformer is overloaded or weak, the secondary voltage drops. A control voltage of 18 V or lower indicates a problem in the 24 V control system.

Transformer problems are usually caused by control problems. A shorted relay sequencer heater will overload the transformer, causing it to fail. Simply replacing the transformer on a system with a shorted relay sequencer heater will only result in another failed transformer. The technician should check the resistance of all 24 V controls whenever replacing a transformer. Any control with a very low resistance across a relay coil should be replaced.

TECH TIP

Electric furnaces use 208–240 V as their primary power. Most replacement transformers have multiple power taps. Refer to the transformer's specifications to make certain that you are connecting the proper leads for the voltage your unit operates on. It is not an acceptable practice to simply assume that you are on a 240 V tap. If you do this on a 208 V system, the secondary voltage will be lower than 24 V. The voltage will be low under some circumstances where there are a number of current-drawing devices on the secondary, such as humidifiers, multiple sequencers, and dampener motors. For example, under these heavy loads, there may not be sufficient voltage and current to operate all of these devices.

61.10 BLOWER RELAY

The blower should come on when the first heating strip comes on and go off when the last heating strip goes off. How this is done depends on the furnace's control

system. Electric furnaces that use separate sequencers for each heating strip typically use a second set of contacts on each sequencer to control the fan. All of these contacts are wired in parallel so that if any sequencer is closed, the fan operates. The blower relay on these furnaces is only used for continuous fan operation or for air conditioning.

Other furnaces use the blower relay to control the fan during heating. These usually require an electric heating thermostat. An electric heating thermostat energizes the G terminal during a call for heat to start the fan. The last sequencer to shut off has a set of contacts wired to control the blower on low speed. This keeps the blower operating when the thermostat is satisfied and the G terminal is no longer energizing the blower relay.

The all-in-one sequencers use a separate set of contacts to control the blower. These contacts will open and close at the same time as those controlling the first heating strip. On this type of system the first heating strip on is also the last one off, so the blower is operating anytime any one of the heating strips is on.

A blower that runs constantly on an electric furnace can be a sign of a sequencer with stuck contacts. This can be checked by measuring the furnace amperage draw. A high amperage draw with no call for heat is an indication of a stuck sequencer. The sequencer can be identified by checking the amperage draw leaving each sequencer until you find the one that is operating all the time. Check the relay sequencer heater voltage to be sure the problem is not in the control circuit.

TECH TIP

Occasionally during new construction metal debris can accidentally be left in a duct system. This debris can fall onto the heating elements because they are located at the top of the unit and are not protected by an evaporative coil the way that gas- and oil-burning systems are. Metal debris falling onto the heating elements will short a portion of the element to ground, turning it on.

UNIT 61—SUMMARY

The voltmeter and clamp-on ammeter are the service technician's most effective tools for tracking down problems in electric furnaces. They can be used to locate defective heating elements, open safety devices, and to check the airflow through the furnace.

Small resistances from poor connections can turn into large problems. Insufficient airflow can be at the root of many component failures in electric furnaces. Broken heating strips, open fusible links, and open thermal overloads are all caused by inadequate airflow.

WORK ORDERS

Service Ticket 6101

Customer Complaint: Poor Heating

Equipment Type: Electric Furnace Installed at the Local Animal Shelter

A service technician is called to inspect an electric furnace that is heating poorly. The furnace has three heating strips, each rated at 5 kW. The technician finds that only one heating strip is pulling current, while the other two have no amperage draw. The technician checks the voltage at these two heating strips and measures a reading of 0 V. He then checks the fusible links and measures 240 V across one of them. Likewise, there is a reading of 240 V across the limit on the other strip.

The technician also notices that the airflow coming out of the registers is very low. Inspecting the air filter, the technician finds that it is packed with animal hair. The technician informs the manager of the animal shelter that the dirty filter reduced the airflow to the point that the heating elements overheated. This in turn caused the fusible link and limit to fail. The technician replaces the fusible link, limit, and air filter and recommends to the manager that in the future the filter be changed once a week.

Service Ticket 6102

Customer Complaint: No Heat

Equipment Type: 15 kW Electric Furnace Installed in a Basement

A service technician answers a no-heat call. Upon arrival, the technician finds that nothing is operating. An initial reading shows that the furnace has 240 V at the fuse block. The technician then measures the voltage at the R and C terminals on the furnace and reads 0 V.

In a hurry to get home, the technician diagnoses a bad transformer and quickly replaces it and then turns the furnace back on. The unit immediately starts, but no sooner has the technician packed up tools but a puff of smoke comes out of the transformer and the furnace stops. Unfortunately, upon checking the new transformer, the technician finds that it is now failed, too.

The technician realizes the unwise mistake that was made in jumping to an immediate conclusion. This time, skipping no steps, the technician begins by checking the 24 V circuits. The second relay sequencer heater is shorted, which led to the transformer failure. The technician replaces the sequencer and transformer and retests the system. This time the system runs and operates correctly.

Service Ticket 6103

Customer Complaint: High Bills

Equipment Type: 15 kW Electric Furnace Installed in Crawlspace

A customer has called complaining of higher than normal electric bills. The technician arrives and the first obvious

thing is that the furnace fan is running continuously. This is the case even with the fan switch set to AUTO and the system switch set to OFF.

The technician measures the furnace amperage draw at 23 A, which indicates that one of the heating strips is operating continuously. Using an ammeter, the technician identifies which set of heating strips it is. The technician then verifies which sequencer is controlling that set of heating strips.

The technician finds that there is no voltage to the relay sequencer heater. This is an indication that the sequencer contacts are not being held closed by the relay but instead must be stuck together. In this case, the sequencer must be replaced. The technician makes the replacement, tests the furnace, and finds that it no longer runs continuously.

Service Ticket 6104

Customer Complaint: Furnace Will Not Run

Equipment Type: 20 kW Electric Furnace with an Electronic Setback Thermostat

A customer calls for help with an electric furnace. When the technician arrives at the residence, the customer explains the problem and provides some detail on the past history of the unit. This past spring, the customer purchased and installed a new electronic setback thermostat from the home supply store down the street. The air conditioner worked fine through the spring and summer months. However, turning the furnace on this fall, nothing happened.

The technician inspects the thermostat wiring, and everything appears to be connected tightly with no loose wires. While inspecting the furnace wiring diagram, the technician notices that the blower motor is controlled by the blower relay in the heat mode and the blower relay is energized by the G terminal. Realizing that this could be the problem, the technician asks the customer for the instructions that came with the thermostat. A section on configuring the thermostat for different systems is shown. The technician modifies the thermostat to bring the fan on in the heat mode, and now the furnace operates correctly.

UNIT 61—REVIEW QUESTIONS

1. List three ways of checking the heating elements of an electric furnace.
2. Describe how a clamp-on ammeter can be used to check an electric furnace.
3. What would be the resistance reading of an open heating element?
4. A technician reads 240 V across the thermal overload to the first strip heater on an electric furnace. What does this mean?
5. List three ways of checking an overload in an electric furnace.

6. What should always be checked when replacing an overload?
7. What should always be checked when replacing a transformer?
8. What is the airflow through a furnace with the following readings:
Voltage at the strips of 235 V
Current draw of 39.5 A
Return-air temperature 72°F
Supply-air temperature 120°F
9. What type of oil should be used when lubricating the motor bearings?
10. Explain how a stuck heating sequencer can keep the fan operating continuously.
11. What is the correct remedy for a wire with one end that has overheated?
12. Why should relay slide-on posts not be sanded to clean off oxidation?
13. How can overlubricating a blower motor be detrimental?
14. What are the two general types of sequencers used on electric furnaces?
15. Describe two ways that electric furnaces control the blower motor.
16. What is the purpose of the white ceramic pieces on the strip heaters?
17. Why is a visual check of the heating strips on an electric furnace difficult to accomplish?
18. Why are terminal and wire resistance values critical in electric furnaces?
19. What are two types of safety that most electric furnaces utilize?
20. Why are the strips on an electric furnace staged to turn on in sequence instead of being energized all at one time?

UNIT 62

Heat Pump System Fundamentals

OBJECTIVES

After completing this unit, you will be able to:

1. describe what a heat pump is.
2. describe the cooling, heating, and defrost cycles.
3. explain the operation of the reversing valve.
4. define *heat source* and *heat sink*.
5. list the types of heat pump systems and configurations.
6. discuss the operation of metering devices and check valves used in heat pumps.
7. explain the purpose of suction accumulators and heating-cycle charge compensators.
8. explain the different types of efficiency ratings used for heat pumps.

62.1 INTRODUCTION

Heat pump systems lead all other forms of heat in terms of efficiency and low operating cost. The demand for heat pumps has increased because of the dramatic increase in the cost for all forms of energy. They must be installed correctly to take advantage of their energy-saving technology. The least efficient system installed correctly will outperform a more efficient system that is poorly installed.

Heat pumps derive their name from the manner in which heat is delivered into the home: they are not “producing” heat, as in the case of fuel-fired or electrical furnaces, but actually “pumping” heat from one area to another. Their efficiency is rated not by how efficiently they consume energy but rather by how efficiently they move it.

62.2 HISTORY OF HEAT PUMPS

The popularity of the heat pump rose with the increasing cost of electrical energy used for heating in residential and small commercial buildings. Heat pumps generally cost less to operate than fossil fuel furnaces and cost only about a third of what it costs to operate electric strip heaters. The heat pump was actually developed by Lord Kelvin in 1852. The first practically applied heat pump was installed in Scotland in 1927. Between 1927 and 1950, heat pumps were installed in hundreds of residential and small commercial settings throughout Europe and the southern part of the United States. Many of these installations were merely air-conditioning units converted to heat pumps by the addition of reversing valves and applicable controls. These early heat pumps had high failure rates because they did not have defrost controls, crankcase heaters, or suction accumulators. Heat pumps acquired a bad reputation as a result of this high failure rate. Although improvements in design made heat pumps more reliable, the early high failure rates caused problems in the market for years. Further, the relatively low cost of energy during this same time period almost destroyed this market.

The demand for heat pumps has grown over the past several decades. The reason for this new interest in heat

pumps is both economic and environmental in nature. Interest in heat pumps has increased in recent years because of growing interest in energy conservation, the rising cost of heating, and mounting concern over the pollution produced by power plants.

62.3 HEAT PUMP CONCEPTS

Like all refrigeration systems and air conditioners, heat pumps transfer heat from one place to another by changing the state of refrigerant. Basically all refrigeration systems are heat pumps; they transfer heat from a heat source at a low temperature to a heat sink at a higher temperature. What makes the heat pump unique is the ability to reverse the direction of refrigerant flow. In the summer it removes heat from the inside air and moves the heat to the outside air. In the winter it will remove heat from the outside air and move it to the inside air. Heat pumps are also called reverse-cycle refrigeration systems.

A review of some basic physics principles will aid in your understanding of heat pumps. Five basic concepts will be discussed:

- Heat exists down to absolute zero, which is -460°F .
- Heat will only flow from a higher temperature region to a lower temperature region.
- Gases become warmer when compressed.
- Most matter can be in a solid (ice), liquid (water), or gas (steam) state.
- The temperature at which a material changes from a liquid to a gas or from a gas to a liquid depends on the pressure at which it is contained.

Concept 1: Heat in Cold Air

For many people, one of the biggest obstacles to overcome in understanding heat pump operation is accepting that heat exists even at very cold temperatures. Since heat is the form of energy that gives molecules their motion and all molecules are in motion, all molecules contain heat. The single exception to this is absolute zero. At absolute zero, molecules do not move, and there is no heat.

Concept 2: Heat Flows from High to Low

Heat will only flow from a higher temperature to a lower temperature, period! The job of the heat pump is to make heat flow from a cooler area to a warmer area. To do this, the heat pump has a low side, which is colder than the cool area, and a high side, which is warmer than the warm area. Moving the heat from the low side to the high side is where the name “pump” comes from.

Concept 3: Compression Raises Temperature, Expansion Lowers Temperature

The high side is created by compressing, or squeezing, the gas. When a gas is compressed, the heat in the gas is concentrated and the temperature rises. This is done by a component called a compressor. Conversely, expanding a gas or liquid causes its pressure and temperature to drop. This is done by the expansion valve. The high side and low side of the system are created by the compressor and expansion valve. Note that the name of the component tells you what it does.

Concept 4: Change of State

Although it is possible to build a heat pump just by compressing and expanding gas, this type of system is not particularly efficient. The change in state of a refrigerant will more dramatically increase the efficiency of the heat pump. Liquids absorb hundreds of times more heat when they change state than when they change temperature. With this in mind, the refrigerant evaporates from a liquid to a gas in the evaporator and condenses from a gas to a liquid in the condenser. Again, note that the name indicates the component’s purpose.

Concept 5: Saturation Temperature and Pressure

Fortunately, the temperature at which evaporation and condensation will take place is controlled by pressure. The increased pressure on the high side raises the condensing temperature, allowing the condenser to reject large amounts of heat while condensing the refrigerant. The decreased pressure on the low side lowers the evaporation temperature, allowing the evaporator to absorb large amounts of heat while the refrigerant evaporates.

Low Supply-Air Temperatures

One obstacle to accepting heat pumps has been the relatively cool supply-air temperatures that heat pumps produce. Customers who have been accustomed to traditional furnaces often object to the cooler supply air from the heat pump. Typical heat pump supply-air temperatures range from 95°F to 110°F. Electric heat has a discharge temperature of 110–125°F, and gas and oil heat supply air in the range of 120–140°F (Table 62-1).

Air at 95° blowing across your body in the winter does feel drafty. The solution to this problem is proper supply register placement. The air from the supply registers should

Table 62-1 Supply-Air Temperature Ranges for Various Heating Systems

Heating Type	Discharge Temperature
Electric strip heat	110–125°F
Gas heating	120–140°F
Heat pumps	95–115°F

not blow directly on the occupants. The heat pump is designed to heat your house, not you!

62.4 HEAT SOURCE AND SINK

Heat pumps are often identified by their heat source and their heat sink. The heat source is where the heat comes from when the heat pump is operating in the heating cycle. Typically, the source can be either air or water. Air-source heat pumps pull heat out of the surrounding air. Water-source heat pumps pull heat out of water circulated through them. The sink is where the heat pump puts the heat. The sink is most often assumed to be air since most heat pumps are designed to condition the air in a building. For this reason, the sink is usually not specified unless it is something other than air. For example, water-source heat pumps only mention the source because the sink is assumed to be air. On the other hand, water-to-water heat pumps use water as both the source and the sink. Table 62-2 lists different heat pump applications by heat source and sink.

62.5 PHYSICAL CONFIGURATION

Heat pumps are available in different physical configurations to match many different applications, including packaged units, split systems, and ductless mini-split systems. Packaged units have all the system components assembled together in one package. They are available to fit different physical space requirements, including units made

Table 62-2 Types of Heat Pumps Listed by Source and Sink

Type of Unit	Source	Sink	Application
Air source	Outdoor air	Indoor air	Heating homes with forced air
Water source/ geothermal	Ground water	Indoor air	Heating homes with forced air
Air to water	Indoor air	Domestic hot water	Heating domestic hot water
Water to water	Ground water	Water loop	Heating homes with hydronic radiant heat

for installation outdoors, over drop ceilings, and through walls or mounted on a wall. Traditional air-source packaged heat pumps are designed for the entire unit to sit outside. Ductwork from inside the building is connected to them. Horizontal water-source packaged units are designed to be installed above a drop ceiling. They are very compact and can easily fit in the small space above a drop ceiling. Packaged terminal heat pumps fit through a sleeve in the wall in motel rooms. Wall-mount packaged units are vertical air-source units that bolt directly to the wall. Ductwork or sleeves pass through the wall into the inside. They are often used for large open meeting rooms.

Split systems break the unit into two separate components that are connected through refrigeration lines. Split systems usually consist of an indoor unit and an outdoor unit connected together through a large gas line and a small liquid line. The large gas line is a low-pressure suction line when operating in cooling and a high-pressure discharge line when operating in heating. Typically, the outdoor section contains the compressor, a coil, a metering device, the reversing valve, and most of the system controls. The indoor unit contains a blower, a coil, and a metering device.

Ductless mini-split systems are similar to split systems, except they are not designed to use ductwork. Instead, the indoor section is designed to be installed in the space being conditioned. Mini-split systems are available that connect up to eight indoor sections to a single outdoor section, providing zoned comfort without ductwork. Another significant difference between traditional split systems and mini-split systems is that the only metering device in a mini-split system is located in the outdoor section. In cooling, the line going inside is cool, low-pressure, saturated liquid because the refrigerant has already passed through the metering device. As a result, both lines are insulated.

62.6 HEATING AND COOLING CYCLES

Heat pumps move heat against a temperature gradient. In the summer they move heat from the inside to the outside, and in the winter they move heat from the outside to the inside. The direction of heat flow is controlled by the direction of the refrigerant flow.

Basic Reverse-Cycle Concept

In the conventional refrigeration cooling cycle (Figure 62-1), heat is absorbed by the indoor coil, the evaporator, and discharged to the outside by the outdoor coil, the condenser. To change from cooling to heating, the indoor and outdoor coils trade functions. The outdoor coil becomes the evaporator, and the indoor coil becomes the condenser. In the heating cycle, heat is absorbed by the outdoor coil, which is now the evaporator, and discharged to the inside by the indoor coil, which is now the condenser.

The heat pump cycle is shown in Figures 62-2 and 62-3. The coils are relabeled as indoor and outdoor because they are now dual purpose. This reduces confusion because the outdoor coil is the condenser in the cooling cycle and the evaporator in the heating cycle. The indoor coil is the evaporator in the cooling mode and the condenser in the heating cycle. The process is reversed by means of a four-way valve called a reversing valve (Figure 62-4).

Figure 62-1 A conventional refrigeration cycle.

Figure 62-2 Heat pump system in cooling mode.

Figure 62-3 Heat pump system in heating mode.

TECH TIP

Remember to tell the owner that the outdoor section will run during the winter heating mode. Some customers may make unnecessary service calls because they believe that the outdoor section only operates in the cooling mode.

Figure 62-4 Heat pump reversing valve.

The Cooling Cycle

During the cooling cycle, the high-pressure/high-temperature discharge gas is directed from the compressor to the outdoor coil (condenser), where it condenses to a high-pressure, high-temperature subcooled liquid. To avoid the restriction of the metering device connected to the outlet of the outdoor coil, a check valve is installed, allowing the liquid to bypass the outdoor metering device. The liquid travels inside through the liquid line, where the indoor check valve closes, forcing the refrigerant through the indoor metering device. The indoor metering device drops the refrigerant pressure and temperature so that heat can be absorbed in the indoor coil. The refrigerant vapor produced in the indoor coil now travels through the reversing valve to the suction accumulator and on to the compressor. The cooling cycle is complete.

The Heating Cycle

The refrigerant flow must be reversed for the heating cycle. Remember, the direction of refrigerant flow through the compressor is always the same; the direction of flow is changed by the reversing valve. In the heating cycle the reversing valve changes position, changing the direction of gas flow. The high-pressure, high-temperature gas from the compressor flows through the reversing valve to the indoor coil. The indoor coil now acts as a condenser, adding heat into the return air from the conditioned area. The hot vapor is condensed, and the temperature is reduced to produce a high-pressure, high-temperature subcooled liquid. The indoor check valve opens and allows the liquid refrigerant to flow around the indoor metering device. Continuing through the liquid line, the liquid refrigerant is forced through the outdoor coil metering device by the closing of the check valve connected in parallel with it. The low-pressure, low-temperature mixture of liquid and vapor refrigerant flows into the outdoor coil, which is now the evaporator. The low refrigerant pressure keeps the refrigerant temperature lower than the outdoor temperature. Since the outdoor air is warmer than the refrigerant, heat is picked up from the outdoor air, evaporating the liquid

refrigerant. This refrigerant vapor then flows through the vapor line, reversing valve, and accumulator to the compressor. The heating cycle is now complete.

62.7 THE REVERSING VALVE

The reversing valve is composed of three main parts: the pilot valve, the main valve, and the solenoid coil. The solenoid coil controls the pilot valve, which in turn controls the suction bleed to the main valve. The purpose of the main valve is to reverse the refrigerant route through the indoor and outdoor coils, thereby exchanging the functions of the condenser and evaporator coils.

The basic operation of a reversing valve can be compared to a solid cylinder sliding inside a hollow tube. Blowing in one end of the tube will shift the cylinder to the other end of the tube. This is how the cylinder inside the reversing valve is shifted, by pressure difference. By imposing the discharge pressure on one end of the reversing valve and the suction pressure on the other end of the valve, the pressure difference will shift the internal cylinder toward the side that is connected to the suction pressure.

Figure 62-5 shows a typical reversing valve. The main valve body is constructed with the permanent suction in the middle of the valve on one side and the permanent discharge in the middle of the valve directly opposite the permanent suction port. The ports leading to the indoor and outdoor coils are located on either side of the permanent suction port. When at rest, the sliding cylinder always straddles two tube openings. One of these openings is always the permanent suction port, which is connected to the low side of the system. The other opening will be either the indoor coil port or the outdoor coil port. This makes whichever coil is connected to the permanent suction via the sliding valve the evaporator. The port that is not covered by the sliding valve is open to the permanent discharge port located opposite the permanent suction port. This makes whichever coil is connected to the uncovered port the condenser. In Figure 62-6, the tube connected to the blue arrow becomes the low side and the tube connected to the red arrow becomes the high side. Note that the two outer tubes swap between the two valve positions.

Heating Cycle: Valve De-energized

Figure 62-7 shows a reversing valve that is de-energized for heating. The solenoid valve is de-energized and the control plunger is down, closing the bottom port vent line connected to the right end of the piston. The top port vent line connected to the left end of the piston is open to the equalizing line. This allows the pressure to bleed off from the left end of the piston to the permanent suction line. This creates a pressure difference across the left-side piston (usually 75–100 psig or greater), which causes it to travel to the extreme left. This movement repositions the slide valve to align the control port from the outdoor coil with the control port leading to the compressor suction, making the outdoor coil the evaporator. This same movement also aligns the compressor discharge with the indoor coil, making the indoor coil the condenser.

Figure 62-5 Connections for a typical heat pump reversing valve.

Figure 62-6 Internal view of heat pump reversing valve.

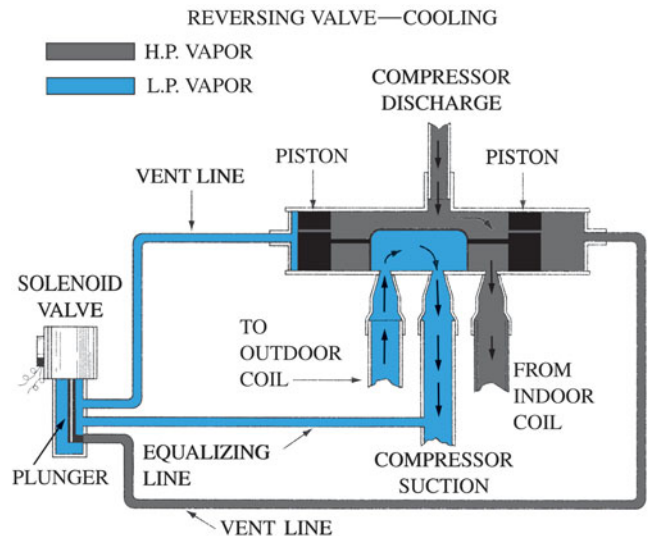

Figure 62-7 Reversing valve in heating position.

TECH TIP

When a reversing valve repositions, refrigerant from the compressor discharge will pass through the piston bleed hole to the vent line, then into the equalizing line and back to the compressor suction. Once the pistons are positioned either to the extreme right or left, the vent line is closed off. On the end of each piston at the vent passage is a tip that seals into a seat to prevent continuous bypass of the hot vapor from the cylinder through the piston bleed hole into the open vent line.

Cooling Cycle: Valve Energized

In Figure 62-8, the solenoid valve is energized and the control plunger lifts, closing the top port vent line connected to the left end of the piston. The bottom port vent line connected to the right end of the piston is open to the equalizing line. This allows the pressure to bleed off from the right end of the piston, which causes it to travel to the extreme right, repositioning the slide valve to align the control port from the indoor coil with the compressor suction, making the indoor coil the evaporator. This same movement also aligns the compressor discharge with the outdoor coil, making the outdoor coil the condenser.

Figure 62-8 Reversing valve in cooling position.

SERVICE TIP

On each end of the sliding piston is a tip that seals into a seat to prevent continuous bypass of the hot vapor from the cylinder through the piston bleed hole into the open vent line. Once the piston is positioned on either side, the tip should seal off the vent line. Leaks at the tip can be detected by a very hot capillary line on the end of the valve.

High efficiency units have less pressure difference between the high and low sides. This reduced pressure difference sometimes causes reversing valves to get stuck halfway through a shift. When this happens, the high- and low-side pressures will equalize through the valve. Valves with four pilot tubes, instead of the usual three, were developed to attack this problem (Figure 62-9). As before, the pilot valve shifts the suction gas to either end of the valve. The extra fourth line on the pilot valve goes to the discharge line and shifts discharge gas to the opposite end. Instead of relying on a bleed port for the high-pressure gas, it is carried via a pilot line directly from the discharge line coming into the reversing valve. No bleed is designed into the valve at all, reducing the chance of unwanted bleed-through during operation and creating a more positive shift. Four-line pilot valve-reversing valves are now being used on most heat pumps.

SERVICE TIP

A reversing valve has a relatively thin copper or brass outside skin. It can be easily damaged if struck by a hammer or wrench. Some technicians feel that reversing-valve problems may be caused by a stuck reversing-valve slide and strike the reversing-valve tube in an attempt to dislodge the stuck slide. Striking a reversing valve with anything can only result in damage to the reversing valve and can never resolve a stuck slide. Never strike a reversing valve.

Figure 62-9 Four-pilot-tube reversing valve.

62.8 THE METERING DEVICES

Since both the indoor and outdoor coils must function as the evaporator, both coils need metering devices. However, only the metering device that feeds the coil acting as the evaporator should be in the refrigerant circuit. In some heat pump designs, check valves are connected in parallel with the metering devices to permit bypassing the metering devices when they are not needed in the circuit (Figure 62-10).

Recently, most manufacturers have been using metering devices that act as both a metering device and a check valve. Flow restrictors with pistons in them are popular in lower-end models. These are like a check valve with a hole drilled through the ball in the check valve. In the forward direction, the piston seats and forces the refrigerant through the hole in the piston, creating a pressure drop. In the reverse direction, the piston lifts off the seat and refrigerant flows around the piston without a pressure drop. Figure 62-11 shows a flow check device in a heat pump and a close-up of the piston from a flow check device.

Some manufacturers design a heat pump system with a fixed metering device for the cooling operation and the thermostatic expansion valve (TEV) for the heating operation. The TEV is a better design choice in the heating mode

Figure 62-10 Check valve in parallel to TEV.

Figure 62-11 Flow check orifice.

compared to the fixed metering device. The TEV can modulate the refrigerant flow over the wide range of temperatures experienced in the heating mode.

Bi-flow TEVs with a built-in check valve are now popular (Figure 62-12). In the forward direction, the check valve seats and forces the refrigerant through the orifice in the expansion valve, creating a pressure drop. In the reverse direction, the ball lifts off the seat and refrigerant flows around the valve seat without a pressure drop.

SERVICE TIP

A bi-flow TEV still has a specific inlet and outlet. If a bi-flow TEV with a check valve is installed backwards, it will not properly meter refrigerant, flooding the evaporator coil.

Figure 62-12 Bi-flow TEV on heat pump split system.

Figure 62-13 Bi-flow TEV on water-source heat pump.

Another form of bi-flow TEVs is used on water-source heat pumps. These valves meter in both directions (Figure 62-13). It is possible to have a single expansion valve on packaged water-source units because the two coils are so close together. Using a bi-flow valve that meters in both directions allows manufacturers to build a unit with only one metering device, eliminating check valves completely. The sensing bulb is not located on the outlet of either coil. Instead, the sensing bulb is located after the reversing valve and before the suction accumulator. In this way the bulb will respond to the refrigerant condition leaving either coil, regardless of mode.

62.9 CHECK VALVES

Checks valves are used in some heat pump designs to direct the flow of refrigerant around the metering device not being used. Two check valves are used: one connected in parallel with the inside metering device and one in parallel with the outdoor metering device. The check valves in the heat pump circuit are vital to ensure that proper pressures are maintained. Today, most heat pump systems use metering devices with built-in check valves, rather than separate check valves. The check valves are still there but are incorporated into the metering devices. (Figure 62-14) shows the flow through the inside and outside flow-check metering devices in both the cooling and heating cycles.

Figure 62-14 The active metering device is shown in the cooling and heating cycle.

The first check valves used in residential and small commercial heat pumps were of the disk type. This valve used a flat disk over a circular flat inset with a spring that had just a light spring constant to aid in closing and still cause very little resistance to refrigerant flow. Where pressure differences occurred rapidly, the disk would be sometimes forced to one side and hang up. This prevented the shutoff of reverse refrigerant flow. An improved version using a steel ball instead of a flat disk was developed. This type of check valve can withstand a heavy reversal of refrigerant flow pressure, especially when the unit completes the defrost cycle.

62.10 REFRIGERANT STORAGE

Since the heat pump operates year round, it must be adaptable to a wide range of operating conditions. These varying conditions translate into significant difference in unit capacity. In simple terms, the heat pump is not always circulating the same amount of refrigerant, so it needs a place for the unused refrigerant to collect. Liquid receivers do not serve this purpose for heat pumps because they are located in the liquid line, where the refrigerant reverses between cycles. Receivers have a definitive inlet and outlet and cannot be reversed. The two storage vessels used in heat pumps are the suction line accumulator and the heating-cycle charge compensator.

62.11 SUCTION-LINE ACCUMULATOR

Accumulators protect the compressor from liquid refrigerant that will leave the evaporator coil during light loads or if the airflow across the coil is reduced for any reason. A suction-line accumulator (Figure 62-15) is a cylinder placed in the suction line, ahead of the compressor, to catch any liquid refrigerant that has not evaporated before it reaches the compressor. In the heat pump, there are three situations where an accumulator can provide compressor protection is needed against liquid slugs:

- **Floodback on the cooling cycle** An air restriction through the indoor coil will lead to a light load, low superheat, and liquid floodback.
- **Floodback on the heating cycle** Excessive frost buildup on the outdoor coil as well as low airflow will lead to a low superheat and liquid floodback.
- **Termination of the defrost cycle** Liquid floodback will always occur when the defrost cycle is terminated.

Accumulators are installed in the piping as near the compressor inlet as possible, as shown in Figure 62-16. The accumulator is located between the reversing valve and compressor suction inlet. Due to the increased volume in this area and the reduction of the refrigerant velocity, the liquid refrigerant and oil drop to the bottom of the container rather than enter the suction opening to the compressor.

The suction gas enters at the upper right. Liquid slugs are directed toward the right-hand wall and run to the bottom. The shape of the deflector directs the inlet flow in a slightly downward tangential direction. There is a metering

Figure 62-15 Suction-line accumulator.

orifice at the bottom of the U-tube return pipe that slowly returns oil to the compressor through the suction line, along with a limited amount of liquid refrigerant. The liquid refrigerant in the accumulator gradually evaporates, entering the compressor as vapor.

Termination of the defrost cycle can cause liquid to flood back to the compressor. The hot gas used to defrost the outdoor coil will condense and turn to liquid refrigerant as it travels through the coil. When the defrost cycle terminates and the reversing valve switches over, the outdoor coil once again becomes the evaporator, and this liquid refrigerant will enter the compressor suction. Without

Figure 62-16 The accumulator goes in the suction line just after the reversing valve.

the accumulator to catch and hold the liquid refrigerant, a liquid surge into the compressor can ruin valves. The accumulator is often sized to hold the entire refrigerant charge of the system to prevent the possibility of liquid carryover into the compressor. Therefore, the refrigerant charge of a heat pump system is very critical.

When a compressor is changed because of a burnout, the accumulator must also be changed because the contamination trapped in the accumulator cannot be removed. Purging or flushing will not clean the accumulator or clear the oil return orifice. Even if the accumulator does not become clogged after a compressor burnout, it can hold a lot of contaminants that the system would be better off without.

SERVICE TIP

During refrigerant recovery, it is sometimes difficult to remove all refrigerant from an accumulator. Some refrigerant can be trapped in the oil at the bottom of the accumulator. As refrigerant is recovered, the accumulator may ice up around the base. If this occurs, recovery can be helped by warming the accumulator. Never use a torch to warm any part of a system during a recovery. Warm water or a heat lamp can be used to warm the accumulator to speed refrigerant recovery.

Figure 62-17 Heating-cycle charge compensator tank.

SERVICE TIP

Pay attention to the inlet and outlet of the accumulator. They are marked and must not be reversed!

62.12 HEATING-CYCLE CHARGE COMPENSATOR

A few manufacturers now use heating-cycle charge compensator tanks (Figure 62-17). The compensator tank is basically an empty can with the gas line running straight through it. The gas line is not open to the tank; it just passes through the tank. Liquid refrigerant enters and leaves the tank through a single small line. This line is connected to the liquid line.

In the heating cycle, the gas line is cold, making the refrigerant in the compensator tank cold. Refrigerant in the liquid line migrates to the charge compensator tank because the refrigerant in the liquid line is at a higher temperature and pressure than the liquid sitting in the compensator tank. This stores the extra refrigerant that is not circulated during the heating cycle (Figure 62-18).

During the cooling cycle, the gas line is hot, making the refrigerant in the compensator tank hot. The liquid refrigerant in the compensator tank leaves the tank and goes into the liquid line because the temperature and pressure of the refrigerant in the tank are now higher than the temperature

Figure 62-18 Compensator tank full during the heat cycle.

Figure 62-19 Compensator tank empty during the cooling cycle.

and pressure of the liquid line. This returns refrigerant to the cycle to be circulated during the cooling cycle (Figure 62-19).

62.13 BI-FLOW FILTER DRIER

The purpose of the filter drier is to remove suspended particles and moisture from the refrigeration system. The bi-flow filter drier (Figure 62-20) is used in the liquid line to prevent contamination of the refrigerant metering devices. Refrigerant flows through the liquid line in one direction in cooling and in the other in heating. If a conventional filter drier were installed in a flow-reversing refrigerant line, most of the contaminants collected in one direction of flow would be flushed back into the system when the reverse flow starts. The design of the bi-flow drier prevents this from happening. The bi-flow drier is similar to having two parallel filter driers with internal check valves that prevent the loss of trapped contaminants. Figure 62-21 shows the internal arrangement of a bi-flow drier. A double-sided arrow is used to indicate the bidirectional flow of the refrigerant through the drier. These driers should be changed every time the system is exposed to the atmosphere.

SERVICE TIP

Filter driers can be used to clean up a system after a compressor burnout. Once the new compressor or condenser is in place, a less expensive model of filter drier can be temporarily installed to trap the major contaminations in the system. A severe burnout may require more than one filter drier change-out. Once the system has been cleaned up, a bi-flow filter drier can be installed permanently.

Figure 62-20 Heat pump bi-flow filter drier.

62.14 HEAT PUMP EFFICIENCY RATINGS

Several different efficiency ratings are used to measure heat pump efficiency. The next two sections describe the different heat pump efficiency ratings and how they are used to compare different units. The four common measures of heat pump efficiency are as follows:

- Energy efficiency ratio (EER)
- Seasonal energy efficiency ratio (SEER)
- Coefficient of performance (COP)
- Heating seasonal performance factor (HSPF)

All of these ratings are used to compare the efficiency of like capacity units. The higher the rating, the higher the efficiency. Higher efficiencies mean lower operating costs. No single rating covers both heating and cooling. EER and SEER rate the cooling efficiency, while COP and HSPF rate the heating efficiency. The temperature and humidity conditions the unit operates in affect the ratings. When comparing ratings, it is important to know the conditions used to produce the rating.

62.15 COOLING EFFICIENCY RATINGS: EER AND SEER

A system's EER and SEER are crucial specifications when choosing equipment. The Federal Department of Energy (DOE) mandates minimum EER and SEER ratings for different types of equipment. The EPA Energy Star program also specifies EER and SEER ratings for units to receive the Energy Star label.

Figure 62-21 Internal operation of a bi-flow heat pump filter drier.

EER: Energy Efficiency Ratio

The energy efficiency ratio (EER) is the number of cooling BTUs accomplished by each watt of electricity used at a given condition. EER is calculated by dividing the cooling capacity in BTUs per hour by the electrical consumption in watt-hours. EER is calculated for a specific condition, normally AHRI rating condition A: 95° outdoor ambient, 80°F dry-bulb, and 67°F wet-bulb indoor air. EER is a steady state measurement. The system is operated long enough to ensure that any startup fluctuations in energy use and cooling capacity have passed. EER calculates the efficiency at one specific condition, but air-conditioning systems operate across a range of conditions. Therefore, the SEER test standard was developed to check the equipment operation across the normal operating outdoor conditions.

SEER: Seasonal Energy Efficiency Ratio

The seasonal energy efficiency ratio (SEER) is the number of cooling BTUs accomplished by each watt of electricity used over a season. Readings are not actually taken over an entire season. To simulate the total cooling capacity and watt-hour use over a season, units are operated at three different specific steady state test conditions (Table 62-3). A fourth test, which cycles the unit on and off during the test, is used to determine the effect of cycling. Additional tests are required for two-stage and variable-capacity equipment. The results of these tests are plugged into a complex formula that calculates the SEER rating. For most equipment, this is very close to the efficiency of the equipment at 82°F outdoor ambient with 80°F dry-bulb and 67°F wet-bulb indoor return air. Since most air conditioners are more efficient at 82°F outside than at 95°F outside, their SEER rating is normally higher than their EER rating.

TECH TIP

It is important to understand that EER and SEER ratings for split systems are for matched systems, not a condenser by itself. The equipment must be installed with an AHRI matched coil for the rating to be accurate.

Table 62-3 Seasonal Energy Efficiency Testing Conditions

Condition	Outdoor Ambient	Indoor Temperature
A	95°F	80°F dry bulb 67°F wet bulb
B	82°F	80°F dry bulb 67°F wet bulb
C	82°F	80°F dry bulb 57°F wet bulb

62.16 HEATING EFFICIENCY RATINGS: COP AND HSPF

A system’s COP and HSPF are crucial specifications when choosing equipment. The DOE mandates minimum HSPF ratings for different types of equipment. The EPA Energy Star program also specifies HSPF ratings for units to receive the Energy Star label.

COP: Coefficient of Performance

The coefficient of performance (COP) is the ratio of total heat output divided by heat input. COP excludes any supplementary resistance (electric) heat. Since the fan motor adds heat to the air, it is included in this rating. COP is represented by the following formula:

$$\text{COP} = \frac{\text{BTU heat output}}{\text{BTU heat input}}$$

The COP for an electric resistance heater is 1. In other words, the electric heat output in BTUH is equal to the heat equivalent of the input wattage. Watt-hours are converted into BTUH by multiplying the watt-hours by 3.41.

The COP rating for a heat pump is variable. The heat output for an air-source heat pump will depend on the outdoor temperature. The cooler the outdoor temperature, the less heat in the air and the lower the heat capacity of the heat pump. As the temperature drops, the COP drops. The COP of a heat pump is always comparably higher than electric heat except at very low temperatures. The COP of an air-source heat pump can be as low as one at very low temperatures and may approach four at ideal conditions. The higher the COP, the more efficient the operation and the lower the operating cost. Most air-source heat pumps operate in a COP range of 2.0 to 4.0.

Generally, the cost of operating an air-source heat pump is one half to one fourth the cost of operating straight electric heat. The COP rating is not the best way to compare heat pump efficiency because the COP varies with the outdoor temperature. COP also does not take defrosting into account. To truly compare two units on the basis of COP, you would need to know the COP of both units over the range of operating conditions, not just the system design condition.

HSPF: Heating Seasonal Performance Factor

The heating seasonal performance factor (HSPF) is like a SEER for the heating season. Unlike the COP rating, the HSPF is designed to measure performance over an entire season, not just one specific operating point. HSPF is the total heat output of a heat pump, including energy used in defrost, divided by the total electric power in watt-hours. It could be stated as the following formula:

$$\text{HSPF} = \frac{\text{Total Btu heating season output}}{\text{Total heating season watts}}$$

Testing for the HSPF is designed to simulate operation over a season using data collected from three specific operating conditions (Table 62-4). A fourth test is used to

Table 62-4 Heating Seasonal Performance Factor Conditions

Condition	Outdoor Ambient	Indoor Temperature
H1	47°F dry bulb 43°F wet bulb	70° dry bulb
H2	35°F dry bulb 33°F wet bulb	70° dry bulb
H3	17°F dry bulb 15° wet bulb	70° dry bulb

determine the effect of frost accumulation and defrosting. Data from these four tests is fed into a complex formula to calculate the unit’s HSPF. The HSPF of a heat pump is always lower than its SEER.

UNIT 62—SUMMARY

Heat pumps are available as air-to-air, water-to-air, air-to-water, and water-to-water units. Heat pump systems are the most efficient and economical heating systems available because they operate by moving heat instead of directly converting another form of energy into heat. The two coils in the heat pump act as either evaporators or condensers, depending upon the direction of the refrigerant flow. Heat pumps change the direction of refrigerant flow using a reversing valve. A metering device is required for both coils. Check valves built into the metering devices control which metering device is active. Refrigerant is stored in either a suction accumulator or a heating-cycle charge compensator. Efficiency ratings for heat pumps include energy efficiency ratio (EER), seasonal energy efficiency ratio (SEER), coefficient of performance (COP), and heating seasonal performance factor (HSPF). The EER and SEER are for cooling; COP and HSPF are for heating. EER and COP are steady state ratings, while SEER and HSPF are calculated to simulate seasonal efficiency.

UNIT 62—REVIEW QUESTIONS

1. List the types of heat pumps available by combinations of heat source and heat sink.
2. Why is a heat pump called a heat pump?

3. How is the refrigeration cycle reversed in a heat pump?
4. Why are accumulators and/or charge compensator tanks necessary in air-source heat pumps?
5. Describe the operation of the reversing valve.
6. What is the difference between an EER and a SEER?
7. What is the difference between a COP and an HSPF?
8. Why are the coils in an air-source heat pump referred to as the outdoor coil and indoor coil instead of the condenser and evaporator?
9. Explain why there is heat in the air even at cold temperatures.
10. List the physics principles that make heat pump operation possible.
11. Why do most heat pumps have two metering devices?
12. What keeps both metering devices from being in the refrigeration circuit at the same time?
13. What is a bi-flow thermostatic expansion valve?
14. What is the difference between the defrost cycle and the cooling cycle?
15. Show the function of the coils by writing “Evaporator” or “Condenser” in the appropriate box for the following table.

	Cooling	Heating
Outdoor coil		
Indoor coil		

16. Show the function of the metering devices by writing “Active” or “Bypassed” in the appropriate box for the following table.

	Cooling	Heating
Outdoor metering device		
Indoor metering device		

17. Where is the permanent suction line always located on a reversing valve?
18. Where is the permanent discharge line always located?
19. Why are bi-flow filter driers used on heat pumps instead of standard filter driers?
20. How does a flow check piston-type metering device work?

UNIT 63

Air-Source Heat Pump Applications

OBJECTIVES

After completing this unit, you will be able to:

1. describe the operation of a typical heat pump thermostat.
2. explain the effect that outdoor temperature has on heating capacity.
3. explain the purpose of supplemental heat.
4. describe the operation of heat pump defrost controls.
5. list the advantages of air-to-water heat pump systems.
6. list the advantages of mini-split heat pump systems.
7. describe the operation of dual-fuel heat pump systems.

63.1 INTRODUCTION

Air-source heat pumps provide an efficient and economical alternative to fossil fuel furnaces. They are popular because of their ability to provide heating and cooling efficiently from a single system. Air-source heat pumps are the dominant heating and cooling system in the southern portion of the country, surpassing fossil fuel furnaces. Air-to-air heat pumps are the most common type of heat pump. They can be readily applied for residential use. They are less expensive than water-source heat pumps and easier to install than a furnace and air conditioner. Air-to-air systems use air as both the heat source and the heat sink. In heating, the outdoor air is the heat source and the indoor air is the heat sink. They are available as packaged units, with all the components in one cabinet, or as split systems, with the compressor and condenser in one cabinet and the evaporator in another.

63.2 AIR-TO-AIR HEAT PUMPS

Air-to-air heat pumps are the most common heat pumps in use today because they are generally less expensive and easier to install than other types of heat pumps. The basic cycle for an air-to-air heat pump consists of absorbing heat from the air in one space and then rejecting this heat to the air at a different location. In the cooling cycle, the indoor coil is the evaporator and the outdoor coil the condenser. The indoor coil absorbs heat from the inside air and the outdoor coil rejects heat to the outside air. In the heating cycle, this transfer of heat is reversed. The outdoor coil is the evaporator and the indoor coil is the condenser. The outdoor coil absorbs heat from the outside air and the indoor coil rejects heat to the inside air.

TECH TIP

Heat pump indoor coils must have a higher design pressure than regular air-conditioning evaporator coils. Since the indoor coil of a heat pump serves as the condenser during heating operation, it must withstand system high-side pressures.

The indoor coil on a heat pump must be able to withstand the high-side system pressure because it is the condenser in the heating cycle. Typically, air movement across the indoor coil is provided by a blower assembly in a fan coil unit that circulates the air through the supply and return duct system. The coil in a heat pump is normally located on the return side of the blower: the blower draws the air across the coil (Figure 63-1). A propeller fan assembly in the outdoor section provides the airflow through the outdoor coil. Most indoor coils are tube-and-fin coils. The outdoor coils can be tube and fin, spiny fin, or micro-channel coils (Figure 63-2).

Figure 63-1 The blower on a heat pump draws the air across the coil.

Figure 63-2 The outdoor coil on a heat pump may be finned tube, spiny fin, or microchannel.

SERVICE TIP

Because the indoor blower on a heat pump draws air across the indoor coil, heat pumps will not operate properly with the panels removed from the indoor blower section. With a panel off, most of the air just enters through the open panel, bypassing the coil altogether. Operating a heat pump with the indoor panel off will cause the indoor coil to freeze up in the cooling mode. In heating, operating with the panel off will cause the unit to shut off on high head pressure.

63.3 HEAT PUMP THERMOSTATS

Most air-to-air heat pump systems use a single-stage cooling and two-stage heating thermostat. Figure 63-3 shows a common heat pump thermostat. A two-stage thermostat is required for the heating operation. The first stage of heat energizes the refrigeration circuit of the heat pump: the compressor and both indoor and outdoor fan motors. The second stage energizes the auxiliary heat when the heat pump cannot maintain the temperature on its own. Because the compressor operates in both heating and cooling, the Y terminal that controls the compressor contactor is energized in both heating and cooling on a heat pump thermostat. The G terminal that controls the fan relay is also energized in both heating and cooling. The thermostat controls system changeover from heating to cooling by controlling the reversing valve. Most heat pumps today energize the reversing valve in cooling. The O terminal on the thermostat is ener-

Figure 63-3 Typical heat pump thermostat.

Figure 63-4 Selectable O/B terminal on heat pump thermostat.

gized whenever the system switch is placed in the cooling position. The O terminal is used to control the reversing valve on heat pumps that energize the reversing valve in cooling. However, not all heat pumps energize the reversing valve in cooling: some energize it in heating. These systems use the B terminal to control the reversing valve. The B terminal is energized whenever the system switch is moved to the HEAT position. Since few systems use both the O and B terminals, many thermostats now have an O/B terminal that is selectable between the two (Figure 63-4).

SERVICE TIP

Trane and some other manufacturers use B to designate the common side of the 24 V control system. You should never connect a B terminal on an over-the-counter thermostat to the B terminal on one of these units. The thermostat will create a direct short across the secondary side of the transformer when it is placed in the HEAT position. A careful inspection of the unit wiring diagram should indicate if B is being used for common.

If the heat pump is not able to maintain the space temperature within a degree or two of the setpoint, the second stage of heat will be energized. When the heat pump and second-stage heat are operating together, the second stage of heat is known as supplemental heat. Second-stage heat is normally controlled by the W or W₂ terminal. Supplemental, or auxiliary heat, is usually electric strip heat. Less commonly, gas or oil heat can also be used as the auxiliary or second-stage heat.

Besides the familiar HEAT, COOL, and OFF system settings, heat pump thermostats also have an emergency heat setting (Figure 63-5). Emergency heat energizes the auxiliary heat on first stage instead of second stage and does not energize the compressor and outdoor fan at all. This setting is used to provide the customer with heat when a problem exists with the refrigeration system. Emergency heat should be reserved for emergency use since the auxiliary heat is typically more expensive to operate than the heat pump. Heat pump thermostats often have lights to indicate when emergency heat is energized. On some models, a light will indicate that the

Figure 63-5 Thermostat showing emergency heat setting.

second stage of heat is energized and a different light will indicate that the emergency heat is operating. Digital thermostats will also provide operating information within the display screen (Figure 63-6). Some messages may flash on and off, such as built-in compressor protection, which does not allow the compressor to restart too soon after a shutdown.

63.4 AIR-TO-AIR HEAT PUMP CAPACITY

Air-source heat pumps are rated for both heating and cooling capacity. Heat pump cooling capacity is rated like air-conditioner capacity, using the AHRI rating condition of 95°F outdoor ambient and 80°F db 67°F wb return air. Heat pump cooling efficiency is also rated like an air-conditioning system using either EER or SEER. The energy efficiency ratio (EER) gives the cooling BTUH produced per watt-hour of electricity used at a given operating condition. The seasonal energy efficiency ratio (SEER) approximates the cooling

Figure 63-6 Digital thermostat display status.

BTUH per watt-hour produced over a season. See Unit 62, Heat Pump Fundamentals, for more information on EER and SEER. Currently, the minimum SEER rating is 13. The highest EER in a heat pump today is 16, and the highest SEER in a heat pump is 22.

Air-source heating capacity is rated at two conditions: 47°F outdoor ambient and 17°F outdoor ambient. The refrigerant system heating capacity is the combination of the heat absorbed from the outside air along with the heat added by the compressor. The more heat absorbed in the outdoor coil, the higher the heat pump heating capacity is. As the outdoor temperature drops, the heating capacity also drops because the heat pump cannot remove as much heat from the air. Table 63-1 shows the capacity of a typical air-source heat pump. At 47°F, the heating capacity of an air-source heat pump is similar to its cooling capacity. However, the heating capacity at 17°F is typically only about half of the heating capacity at 47°F. The heating seasonal performance factor (HSPF) is used to specify the heating efficiency. It approximates the heating BTUH per watt-hour for a season. The minimum HSPF is currently 7.7; the highest HSPF currently available is 13.

Energy Star is a voluntary awareness, communications, and marketing campaign developed by the U.S. Department of Energy, Environmental Protection Agency (EPA), in 1992 to promote energy efficiency in a multitude of products, including heating/cooling equipment. There are often federal programs that reward consumers financially for choosing Energy Star appliances, including tax credits. The Energy Star label is awarded to those air-to-air packaged units with an EER of 11 or greater, a SEER of 14 or greater, and an HSPF of 8 or greater (Figure 63-7). For split systems, the requirements are an EER of 12 or greater, an SEER of 14.5 or better, and an HSPF of 8.2 or better.

Figure 63-7 Energy Star label. (Courtesy of U.S. Environmental Protection Agency, Energy Star Program)

63.5 AUXILIARY HEAT

Air-source heat pumps heat by removing heat from the outside air and delivering it to the inside. As the outside air temperature drops, the evaporator temperature and pressure must also drop in order to continue to absorb heat. This increases the compression ratio of the compressor pump and decreases its volumetric efficiency. In short, the system loses capacity. At the same time, the system load actually increases due to the increased demand for heat at lower temperatures. At some point, the heat pump's decreasing capacity will not be able to keep up with the structure's increasing load. The lowest temperature at which the heat pump can heat the structure is called the balance point. Below this temperature, auxiliary heat will be required to maintain comfort conditions.

Normally the auxiliary heat is not energized until the system reaches its balance point because auxiliary heat is more expensive to operate. In practice, the auxiliary heat is energized 5°F above the balance point to ensure that the system can handle the demand. The auxiliary heat is also used to re-heat the cool air the heat pump circulates in the defrost cycle.

The auxiliary heat is controlled by the second stage of a two-stage thermostat. The second stage closes approximately 1.5°F below the thermostat setpoint. If the heat pump cannot meet the heating demand, the second stage energizes to bring on the auxiliary heat. Some units also use outdoor thermostats set to 5°F above the balance point. These outdoor thermostats will not let the auxiliary heat come on until the temperature outside drops to their setpoint.

Electric strip heaters are the most common auxiliary heat (Figure 63-8). Since the refrigeration circuit can move heat more inexpensively than the electric auxiliary heaters can produce heat, the auxiliary electric is the second stage

Figure 63-8 Electric strip heater.

Figure 63-9 Strip heaters can be installed in space provided in heat pump.

of heat. It cycles on and off while the refrigeration system continues to operate. The electric strip heaters are normally installed after the blower. Most units have access panels where the strip heaters are installed when the heat pump is installed (Figure 63-9). Electric strip heaters normally come in 5-kW increments. A 5-kW strip heater produces 17,000 BTUH when operated on 240 V. The same heater operated on 208 V produces only 3.6 kW and 12,300 BTUH.

The load of the building being conditioned and the capacity of the equipment being used to condition it determine a system's balance point. This means that the balance point of a heat pump installed in your house would be different than the balance point of the same system installed in your neighbor's house. The amount of auxiliary heat required increases substantially as the outside air temperature decreases. This can be seen in Table 63-2, which is based on an inside temperature of 70°F. At an outdoor temperature of 40°F and 5 kW of auxiliary electric heat, the heating capacity for the unit would be 37,440 BTU/hr. If the outside temperature dropped to 10°F, an 8-kW heater would be required to maintain roughly the same heating capacity, which would now be 38,110 BTU/hr. If the temperature dropped as low as -10°F, a 10-kW heater would be required.

TECH TIP

An air-to-air heat pump will operate continuously when the outdoor temperature is below the balance point. The auxiliary heat is turned off before the first stage of the thermostat is satisfied, so the heat pump continues to run. Since the refrigeration system cannot provide enough heat below the balance point to meet the load, the first-stage heating thermostat will not be satisfied. The auxiliary heat will cycle on and off to maintain a temperature just below the thermostat setpoint.

63.6 OUTDOOR AMBIENT THERMOSTAT

The outdoor ambient thermostat (OAT) controls the operations of the supplemental heat. The remote sensing bulb is mounted outside the unit in a location where it will not be influenced by airflow from the unit (Figure 63-10). The outdoor thermostat is set low enough to prevent the operation of all the electric heating elements when the outdoor temperature is mild (Figure 63-11). For example, a common setting is 40°F. The purpose of this control is to prevent unnecessary operation of electric heat should the thermostat operator turn the temperature setting high enough to operate the heat pump and the supplemental

Figure 63-10 Outdoor ambient thermostat sensing bulb.

Figure 63-11 Outdoor ambient thermostat.

TECH TIP

New energy codes that have been adopted in many cities and states require an outdoor thermostat on all installations. The outdoor thermostat must lock out the supplemental heat when the outdoor temperature is above 50°F. This allows the compressor to provide heat for the resident and keeps the more expensive energy-consuming supplemental heat strip off.

heat. The outdoor thermostat is bypassed when the heat pump thermostat is switched to the emergency heat mode.

63.7 DEFROST CYCLE

Frost forms on the outdoor coil at low ambient temperatures because the outdoor coil must operate below the outdoor temperature. It is important to keep the outdoor

Conditions: 860 CFM; indoor air at 70°F DB

(Courtesy of Goodman Global Group, Inc.)

coil cleared of frost because the system efficiency drops when frost builds to the point that it blocks airflow. The defrost cycle is required to melt the frost before it interferes with system operation. The defrost cycle is similar to the cooling cycle, except that the outdoor fan is de-energized and the strip heaters are energized. The outdoor coil switches from being an evaporator to now being the condenser. This allows for hot vapor to pass through the outdoor coil to help defrost any frost buildup. However, an adverse result from operating in this mode will be that the unit is air-conditioning the house in the middle of winter! To offset this effect, the outdoor fan is de-energized and the auxiliary heat is energized during the defrost cycle. The auxiliary heat is energized to prevent 60°F air from blowing in the house.

When the defrost cycle is initiated, the reversing valve reverses to send hot gas to the outdoor coil and the outdoor fan is de-energized. In defrost mode, the indoor coil becomes an evaporator, removing heat from the indoor air. Without energizing the auxiliary heat, the air delivered to the conditioned space would be cold air rather than hot air. To reduce this effect, the auxiliary heat comes on for the duration of the defrost cycle to reheat the air. The result is that the air is a slightly warm 80°F instead of a chilly 50°F.

TECH TIP

Tell your customer about the steam that will come off the outdoor unit during winter defrost cycles. Some owners may be startled when they see the steam coming from the outdoor coil. The owner may think this steam is smoke and may believe the outdoor section is on fire. Prepare owners so that when they see this, they will be assured the system is running properly.

The defrost control must determine when to start a defrost cycle and when to stop it. Starting a defrost cycle is called initiation; stopping a defrost cycle is called termination. If the defrost cycle is not initiated frequently enough, the outdoor coil will become frozen over with a sheet of ice. If the defrost cycle is initiated too often, the efficiency of the system is decreased and energy is wasted, increasing the cost of operation. Some method in addition to temperature must be used for initiation. If temperature alone were used for initiation, the system would not be able to operate normally below freezing. Most defrost controls use temperature to sense when they should terminate the defrost

Figure 63-12 Simple time temperature defrost timer.

cycle. The two most common types of defrost controls are time temperature and temperature differential.

63.8 TIME TEMPERATURE DEFROST CONTROLS

The time-initiated temperature-terminated defrost control board uses a timing circuit and an open-on-rise defrost thermostat to control the defrost cycle (Figure 63-12). The timing circuit times the amount of compressor operating time during the heating cycle. It will not allow a defrost cycle until after a specific amount of compressor operating time. The most common defrost periods are 30, 45, 60, and 90 minutes. This time period is adjustable on the defrost board by moving a jumper or a selector switch (Figure 63-13). When the defrost time is reached, the timer will try to initiate the defrost cycle. However, if the temperature is not low enough, generally below 26°F, the defrost thermostat (Figure 63-14)

Figure 63-13 The defrost period is selectable with a jumper.

Figure 63-14 Defrost thermostat.

will not close and the defrost cycle will not begin. The timer will reset, and a new countdown starts until the next defrost begins. Once a defrost cycle has been started, it will continue until the defrost thermostat opens, usually somewhere around 50°F. The placement of the defrost thermostat is critical for correct operation. Its location can vary a great deal from one model unit to another. The timer has a failsafe defrost period, usually 15 to 30 minutes. Even if the defrost thermostat fails to open after the failsafe period of defrost operation, the defrost control terminates the defrost cycle and puts the heat pump back into heating mode.

63.9 DEMAND DEFROST CONTROLS

The major advantage of time temperature defrost controls is reliability. The main disadvantage is that forcing a defrost every hour of operation in cold weather can cause many unnecessary defrosts that waste energy. Just because the coil temperature is below freezing does not necessarily mean there is frost on the coil. A demand defrost control senses some aspect of unit operation to determine when there is actually frost on the outdoor coil. Methods used for demand defrost controls have included the following:

- Air pressure drop across the outdoor coil
- Compressor amp draw
- Temperature differential

Temperature differential has proven to be the most reliable. Nearly all demand defrost controls today use the temperature differential method. A temperature differential defrost control uses thermistors to sense the outdoor coil temperature and the outdoor air temperature. Under normal operating conditions, the temperature difference between the coil and the outdoor air remains fairly constant. When the frost on the coil builds to the point that it is blocking airflow, the coil temperature starts to drop. Since only the coil temperature is dropping, the temperature difference between the coil and the air is increased. The temperature differential control initiates a defrost whenever the difference between the coil and the air increases for a prolonged

period of time. Most demand defrost controls have some failsafe period built in to force a defrost after several hours of operation below freezing. Like time temperature controls, temperature differential controls terminate the defrost when the coil temperature has reached around 50°F. They also have a failsafe defrost operation time that will terminate a defrost cycle after 15 to 30 minutes.

TECH TIP

The defrost thermostat on a time temperature defrost control is usually an open-on-rise thermostat. It is a mechanical switch that is either opened or closed. Its resistance should be 0 when it is closed, calling for a defrost period, or infinite when it is open, terminating the defrost period. The thermistor sensors on a demand defrost control are temperature sensors with a measurable resistance at all times. Their resistance changes with temperature. The two are not interchangeable.

63.10 CRANKCASE HEATER

The crankcase heater (Figure 63-15) is an electrical heating device that is inserted in the compressor crankcase or around the lower part of a hermetically sealed compressor shell. It provides heat to evaporate any liquid refrigerant that reaches the crankcase during the OFF cycle. At shut-down, the compressor will often become the coldest part of the system. The cold compressor creates a low-pressure condition and condenses the vapor refrigerant into a liquid. This process of attracting and condensing refrigerant is known as migration.

The crankcase heater protects the compressor when starting by vaporizing any liquid refrigerant that may enter the compressor during the OFF cycle. On many compressors, the crankcase heater only operates during the OFF cycle. On others it may be energized all the time. The crankcase heater may be fastened to the bottom of the compressor crankcase or it may be inserted in a tube located in the crankcase. When it is wrapped around the compressor shell it is referred to as a bellyband crankcase heater.

Liquid refrigerant in the crankcase can be very damaging to the compressor. If refrigerant collects in the crankcase, it mixes with the oil. This creates a condition known as a flooded start. When the compressor cycles on, the crankcase pressure quickly falls to the level of the suction pressure. This causes the liquid refrigerant mixed with oil to boil violently, creating foam, which can result in compressor slugging and the oil being pumped from the compressor crankcase. At a minimum, the liquid refrigerant in the compressor crankcase dilutes the oil, causing improper lubrication, which shortens the life of the compressor mechanical parts.

62.11 PRESSURE SWITCHES

Most heat pumps have a high-pressure switch that detects the pressure on the discharge side of the compressor (Figure 63-16). The high-pressure switch has a set of open-on-rise

(a)

(b)

Figure 63-15 (a) Immersion-type crankcase heaters must be installed with thermal mastic; (b) external-type crankcase heater (sometimes referred to as “bellyband”).

Figure 63-16 High-pressure switch.

Figure 63-17 High-pressure switch with manual reset.

contacts that open when the system high-side pressure exceeds a safe level. Many high-pressure switches are the automatic reset type. Once the high-pressure condition drops, the switch will close, allowing the heat pump to operate again. One problem with this type of control is that the condition causing the pressure switch to trip may go undetected for a long time. A manual-reset high-pressure switch does not automatically close its contacts on a drop. A technician will need to push a button on the pressure switch to complete the electrical circuit and allow the heat pump to operate again (Figure 63-17). You should always determine the reason for the high-pressure condition after resetting it. The tripped switch is not the problem but a symptom.

Air-source units typically do not use a traditional low-pressure switch because the suction pressure can be very low in normal operation during cold weather heating. Instead, they use a loss-of-charge low-pressure switch. A loss-of-charge switch is installed in the high side of the system but has a close-on-rise switching action similar to a low-pressure switch. The switch is designed to open when the high-side pressure drops abnormally low due to lack of refrigerant.

63.12 DISCHARGE-LINE THERMOSTAT

A discharge-line thermostat is an open-on-rise thermostat that opens to keep the compressor from overheating. It can be attached to the discharge line (Figure 63-18) or to the head of compressor. A discharge line temperature in excess of 250°F indicates overheating of the compressor. If the discharge line temperature is 250°F, the internal temperature of the compressor is around 300°F. At this temperature, the oil will begin to break down. Discharge-line thermostats typically open between 200°F and 250°F. Excessive discharge temperatures are caused by low charge, high compression ratios, and high discharge pressures.

63.13 PACKAGED UNITS

Packaged systems have all of the components in one preassembled unit, as shown in Figure 63-19. Typically included are electric heat strips located in the blower discharge area.

Figure 63-18 Discharge line thermostat.

Figure 63-19 Packaged heat pump components

Some type of auxiliary heat is required, except in semitropical climates such as that in Southern Florida. The easiest type of auxiliary heat system to incorporate into the heat pump assembly is the electric strip heater. When a gas or oil furnace is used for auxiliary heat, the combined system is referred to as being dual fuel.

Air-source heat pump package systems require no refrigerant line connections to be assembled. This advantage reduces installation costs. However, a disadvantage is that packaged units are somewhat limited in configuration types and to where they must be located. They are available as side discharge, bottom discharge, or wall mount. Bottom-discharge units are typically mounted on flat roofs or a curb. They are sometimes referred to as curb-mount units. Side-discharge duct connections can be arranged in two ways: over-under or side-by-side. Over-under units have the supply duct over the return duct (Figure 63-20). Side-by-side units have the return and supply ducts beside each other (Figure 63-21).

Some units are convertible from side discharge to bottom discharge. They accomplish this with removable panels

Figure 63-20 Over-under package unit with panels removed.

Figure 63-21 Side-by-side packaged unit.

on the bottom and sides of the unit where duct can connect. Typically these units arrive with both sets of panels in place. For bottom discharge, remove the bottom panels; for side discharge, remove the side panels (Figure 63-22).

Wall-mount packaged units mount to the exterior wall of a building. The air moves through two large holes in the wall. The return air is drawn in at the bottom of the unit, and the supply air leaves at the top. Many wall-mount units are installed like giant room air conditioners, with no ductwork. The unit is bolted to the wall and two large grills cover the return- and supply-air openings. This is typical in trailers that serve as temporary offices or classrooms (Figure 63-23).

63.14 SPLIT SYSTEMS

Split systems have two components: a condensing unit that is installed outside and a blower coil that is installed inside (Figure 63-24). The condensing unit consists of a

Figure 63-22 Convertible packaged unit.

Figure 63-23 Wall-mount unit.

compressor, reversing valve, outside air coil, outdoor fan, and outdoor metering device (Figure 63-25). The blower coil contains the indoor fan, indoor air coil, and indoor metering device (Figure 63-26). The indoor coil is located in front of the blower so that air is drawn through the coil. By drawing the air through the coil, air travels more evenly over the coil and all of the coil area is used. With electric resistance auxiliary heat, the electric heat strip is located in the upper section of the blower discharge area, behind the control assembly and enclosing panel.

Figure 63-24 Split-system air-to-air heat pump.

Figure 63-25 Split-system heat pump outdoor unit components.

The condensing unit and blower coil are connected by two refrigerant lines: a gas line and a liquid line. The liquid line always contains high-pressure liquid, regardless of the cycle; however, the direction of the liquid changes. Only one metering device is active at a time. This is determined by

the internal check valve inside the metering device. When liquid flows from the liquid line into the metering device, the check valve closes, and the metering device becomes active. When liquid flows from the coil out of the metering device, the check valve opens, allowing full, unrestricted flow. In cooling, the liquid is traveling from outside to inside and the indoor metering device is active. In heating, the liquid is traveling from inside to outside and the outside metering device is active. The gas line changes from a low-pressure suction line in cooling to a high-pressure discharge line in heating. That is why it is called the gas line: the refrigerant in it is always gas.

SERVICE TIP

There is a gauge access port on the gas line at the condensing unit. However, it cannot be used to measure the system suction pressure in heating because the gas line is a discharge line during the heating cycle. Heat pumps all have a third port that is always low pressure. You must find it and install your gauges there.

An advantage of the split system is that it can be used in a wide range of vertical, horizontal, or downflow applications. However, the installation cost is higher than for a comparable packaged system. Split systems are brought to the job site in several individual parts, including an air handler, indoor coil, auxiliary heat source, outdoor unit, and interconnecting wiring and copper tubing (Figure 63-27). All of these components need to be connected together. Installing a split system requires brazing, cutting pipes to length, evacuating, and charging the system.

Figure 63-26 Heat pump blower and cooling coil indoor unit.

Figure 63-27 Split air-to-air heat pump system. (Courtesy of Goodman Global Group, Inc.)

Figure 63-28 Split-system heat pump mounted above the ground for snow.

TECH TIP

The outdoor unit on a heat pump has to be mounted above the ground in areas where snowfall accumulates, at a height above the average annual snowfall for the region (Figure 63-28).

63.15 TWO-STAGE HEAT PUMPS

Many manufacturers now offer heat pumps with two-stage compressors (Figure 63-29). These systems have two stages of cooling and three stages of heat: two stages of compressor heat and one stage of supplemental heat. Staged systems operate at the low compressor capacity most of

Figure 63-29 Two-stage compressor.

Figure 63-30 Board to control two-stage compressor.

the time. This allows them to use less energy when the full system capacity is not needed. Operating on low capacity also produces longer run times, reducing the energy loss from cycling on and off. These systems require thermostats capable of two stages of cooling and three stages of heating. The two-stage compressors are controlled by a board that controls the operation of an unloading solenoid in the compressor (Figure 63-30). Many heat pumps with two-stage compressors have built-in communicating controls. They are designed to work with indoor blowers that use variable-speed brushless DC motors (ECM) and communicating controls. When the heat pump is operating at low capacity, the indoor blower speed reduces to match the system capacity. When the thermostat calls for high speed, the indoor blower speed ramps up to match the increased compressor capacity. Heat pump systems using two-capacity compressors and ECM motors typically achieve efficiencies of 20 SEER and 10 HSPF.

63.16 MINI-SPLIT HEAT PUMP

Most mini-split heat pumps do not require ducts. This makes them easier to install. This type of unit is generally sized to heat and cool one room and have its own thermostat for that space. As an example, a building with four major rooms would have a mini-split located in each one. The indoor unit is relatively small, as little as 7 in deep, and can be mounted to the ceiling or hung from a wall (Figure 63-31). The thermostat will generally have a remote control for ease of operation. A significant difference between most mini-split systems and traditional split systems is the location of the metering devices. Most mini-split heat pumps have a single electronically controlled metering device located outside in the condensing unit. There are no metering devices in the indoor coils. As a result, both refrigerant lines are insulated, because in cooling, both lines are cold.

Figure 63-31 Mini-split heat pump system.

Some mini-split units, called multi units, have multiple indoor coils attached to a single outdoor unit. Multi units are available that allow up to eight indoor units to connect to a single outdoor unit. These usually have a variable-speed compressor, allowing the compressor capacity to match the load. The unit uses less energy at reduced capacity, saving energy. This type of system will operate more efficiently than several smaller systems cycling on and off.

There are some distinct advantages for this type of system. Since a duct network is not required for the air to travel through, these units have no duct losses. In poorly insulated duct systems, these losses can be as high as 30 percent or more, especially for ducts running through an unconditioned space, such as an attic. The connection between the outdoor and indoor units is also usually fairly simple, with the only requirement consisting of a 3-in-diameter hole through the exterior wall. The indoor section is sleek and attractive and will not block incoming light, as a standard window-mounted air conditioner will. Each space has its own thermostat, which allows for reducing the cooling or heating supply when no one is there, which will save on energy costs.

Some disadvantages of the mini-split include its high initial cost and more refrigerant lines, wiring, and drains to run. Installing multiple mini-split systems in a house will generally have a higher initial cost than a single central system with air distribution. Every indoor unit needs its own set of refrigerant lines, wiring, and drain. So while there is no ductwork to run, there are more wires, refrigerant lines, and drain lines to run.

63.17 DUAL-FUEL HEAT PUMP SYSTEMS

Gas or oil furnaces can also be used for auxiliary heat. A heat pump system that uses a gas or oil furnace as the auxiliary heat is known as a dual fuel, or hybrid heat pump system. In a dual-fuel system, the heat pump operates above the balance point and the furnace operates below the balance point. In a dual-fuel system, the indoor coil is installed after the furnace in the airstream (Figure 63-32). When a gas or oil furnace is used for supplemental heat, the heat pump shuts off when the furnace comes on because the hot air from the furnace passing over the indoor coil causes extremely high head pressures in the heat pump. This type of system requires the coordination of the heat pump and the furnace operation. This is normally accomplished using

Figure 63-32 Heat pump coil mounted on furnace to form dual-fuel heat pump system.

either a separate dual-fuel add-on control board or a thermostat designed for a dual-fuel system. A few heat pumps and furnaces now have dual-fuel control capability built into their control systems.

63.18 DUAL-FUEL HEAT PUMP PACKAGED SYSTEM

A packaged dual-fuel heat pump system combines both an air-to-air heat pump and a gas furnace into one packaged system (Figure 63-33). The indoor coil on these systems is located in the return air, before the gas heat exchanger. This type of unit often uses a two-stage compressor, a variable-speed blower motor, and a dual-fuel thermostat.

Figure 63-33 Dual-fuel heat packaged heat pump.

The heat pump will provide cooling in the summer season and heating during moderate winter conditions. When the temperature drops below the balance point, the system automatically switches to gas furnace heating. At this lower outside temperature, gas becomes the more economical heating source and also provides for greater heating capacity than the heat pump.

63.19 SOLAR-ASSISTED HEAT PUMPS

Two types of solar-assisted heat pump systems are currently available: thermal and photovoltaic. Thermal solar panels heat water circulated through them. Photovoltaic solar cells generate electricity. Thermal solar-assisted systems use thermal solar collectors to heat water. This hot water is used for both domestic hot water and additional space heating in the winter. Heat is added by circulating the solar-heated water through a water coil in the heat pump indoor blower section (Figure 63-34). Some heat pump systems are now available with a hot-water coil and controls preinstalled for adding thermal solar hot water. This system

Figure 63-34 This air-to-water heat pump system also can use solar energy from thermal solar collectors for heat.

Figure 63-35 Installing a 5-kW solar array for use with two solar-assisted air-source heat pumps.

required the addition of solar thermal collectors, hot-water storage, circulating pumps, and solar controls.

Photovoltaic-assisted heat pumps have two power supplies: one from the power grid and another from the solar cells (Figure 63-35). The heat pump uses the solar-generated electricity to reduce its power consumption from the power company when the unit is operating and solar power is available. When solar power is available and the unit is not operating, the power is sold back to the power company. If the solar collectors are generating more electricity than the system requires, it is possible to operate the system entirely from solar power and sell the surplus back to the power company. These systems require photovoltaic solar cells and an extra disconnect. Other electrical components normally required to use photovoltaic cells with alternating current devices include a voltage regulator and power inverter. The solar cells used with solar-assisted heat pumps greatly simplify the installation by having internal voltage regulators, power inverters, and safety shutoff controls built in. This eliminates the need for these items and the electrical connections between them. Installation is very similar to a regular air-to-air heat pump, except that there are two power supplies feeding the unit. As a safety feature, these systems are specifically designed to operate only when they are connected to the power grid. If the solar cells do not see the power from the power company, they automatically shut down their output.

63.20 AIR-TO-WATER HEAT PUMP SYSTEM

The air-to-water system is a relatively new application and involves more equipment as compared to a basic air-to-air system. These are often referred to as reverse-cycle chillers (RCCs). RCCs have an outdoor air coil and a water coil connected to hydronic systems inside the house. In heating, a reverse cycle chiller moves heat from the outdoor air into the water storage tank inside. The outdoor air coil is the evaporator and the water coil is the condenser. This hot water is circulated to a large insulated tank of water called

Figure 63-36 A buffer tank as compared to an electric hot-water heater.

a buffer tank. It is called this because it balances out any fluctuations in load to provide more constant and steady heating and cooling. The water from the buffer tank can be circulated to a coil in an air handler for forced-hot-air systems. This application can also be arranged to accommodate forced-air systems with multiple zone radiators, as well as radiant floor heating systems, blower coils, or even to domestic hot-water heaters. Figure 63-36 shows a small buffer tank that is comparable in size to a hot-water heater but with additional connections for the refrigerant coil and a connection for the air-handler coil.

In cooling, the water circulating through the water coil does not circulate through the buffer tank. Instead, it circulates only between the heat pump and a blower coil. Heat is absorbed from the water and rejected to the outdoor air at the air coil.

There are several advantages of an air-to-water system. There is little to no effect on the warm water air temperature being supplied to the building when the outdoor coil enters the defrost mode because the heat for defrost comes from the buffer tank, not the building. Cold air during defrosting is a common complaint for air-to-air systems. The electric heat that is required to come on during the defrost mode for an air-to-air system is not required because the heat is coming from the buffer tank, therefore saving energy. The air-to-water system will generally operate with higher efficiencies at lower outdoor temperatures as compared to air-to-air systems. The large heat sink of water will maintain a more constant temperature when the outside temperature drops, reducing the amount of supplemental electric heat required.

63.21 HEAT PUMP HOT WATER HEATERS

Heat pump hot water heaters are air-to-water systems that use the air surrounding the unit as the heat source and the water in the hot water system as the heat sink. They move heat from the air surrounding them into the domestic hot water tank. These heat pump systems are marketed in small unit sizes for water heating. This system is used to replace traditional electric water heaters. The initial cost

Figure 63-37 Heat pump hot-water heater.

of a heat pump water heater is 4 to 5 times as much as a traditional electric water heater, but they operate for half the cost. Payback on the additional cost is typically less than 5 years. Residential units are available in the capacity range of 6,000 to 12,000 BTUH. They may be incorporated into a package unit along with a hot-water storage tank or as an add-on unit for existing storage tanks (Figure 63-37).

Larger units are available for commercial application to provide hot water and spot cooling. The unit becomes the primary heat source for domestic or small commercial hot-water use, with the heat source of the water heater as backup. The higher efficiency rating or COP (coefficient of performance) of the heat pump water heater will supply hot water at approximately half of the cost of a traditional electric water heater.

UNIT 63—SUMMARY

Air-to-air heat pumps are the most common type of heat pump. They use air as both the heat source and the heat sink. In heating, the outdoor air is the heat source and the indoor air is the heat sink. They are available as packaged units, with all the components in one cabinet, or as split systems, with the compressor and condenser in one cabinet and the evaporator in another. Air-to-air heat pumps require supplemental heat, which is normally provided by electric heat strips. A dual-fuel heat pump uses a gas or oil furnace for supplemental heat. Air-source heat pumps must have a defrost cycle to clear them of frost during operation at temperatures below freezing. The two common types of defrost controls are time temperature and demand defrost. The best system is the one that is properly designed, sized,

and installed while meeting the needs of the specific application. Properly designed and installed heat pump systems can save the customer money and provide for four-season heating and cooling needs.

WORK ORDERS

Service Ticket 6301

Customer Request: Split-System Retrofit

Equipment Type: Existing Split System to Be Replaced by Air-Source Heat Pump

The sales representative meets with the customer to discuss the options for upgrading her current heating and cooling system. During a recent service call, the technician recommended that the outside air-conditioning system be replaced, as it was old and becoming expensive to maintain. However, the small gas furnace and cooling coil located in the basement are still in good operating condition. When the homeowner told the technician that the price of heating with gas was becoming increasingly expensive, he recommended a heat pump system. The technician had recently been installing heat pumps throughout the community and their performance was receiving favorable reviews.

The sales representative agrees with the technician's advice. The latest 15-SEER air-to-air heat pump systems the company has been carrying as a product line are much improved over earlier versions. The energy efficiency is very good, and in this moderate climate the air-to-air system with on-demand defrost works exceptionally well. Rather than replace the gas furnace, it can remain in place and be used for auxiliary heat if necessary. The customer agrees to the retrofit, and the existing outdoor unit is replaced with an air-to-air heat pump. The existing coil is replaced with one that is designed for heat pumps and is an AHRI match for the new heat pump condensing unit.

Service Ticket 6302

Customer Complaint: Frequent Cycling and High Operating Cost

Equipment Type: Mini-Split Heat Pump

The customer complains to the technician that the new mini-split system that was recently installed by a local discount supply house is frequently cycling, using more electricity than originally anticipated. Almost immediately, the technician realizes that the system is much larger than what would normally be required for a space of this size. The technician asks the customer who had determined the sizing requirements for the mini-split. The customer explains that the unit was a closeout model and on sale for a very reasonable price. As a further incentive, the discount supply house where the mini-split was purchased offered free installation.

The technician asks if the mini-split could be returned, because it is oversized. The customer shakes his head no, because this was a sale item and no returns were allowed. The technician says that someone from the supply house should have offered to help in sizing the unit to make sure it would meet the application. The technician recommends that the customer talk to someone at the discount supply house about this situation but cannot offer any solution other than replacing the unit with an appropriately sized mini-split.

Service Ticket 6303

Customer Request: New Installation

Equipment Type: Wall-Mounted Packaged Heat Pump

A sales consultant is asked to recommend a heating and cooling system for an add-on classroom trailer that is to be located outside the main building at the local high school. The building maintenance supervisor has requested that the installation be completed quickly and within a limited budget. There are a number of options that can be considered. One recommendation is for a split-system air-conditioning unit with a small gas-fired furnace.

The building maintenance supervisor asks the sales consultant about the possibility of installing a heat pump system. The sales consultant acknowledges that these are being used more often, but auxiliary electric heat will need to be included for the colder months. This will add to heating costs come winter. However, a wall-mount packaged heat pump is the least costly alternative for installation. No ductwork will be needed because the building is one large room. The installation can be done in 1 or 2 days. Since the classroom trailer is not a permanent structure, this is considered to be the best solution for the building maintenance supervisor.

Service Ticket 6304

Customer Request: New Installation

Equipment Type: Air-Source Split-System Heat Pump

Dr. Studdart is the dean of the Technical Division of the local Technical College and has learned about ground loop systems from the air-conditioning faculty. He is in the process of building a new home, and this type of system for heating and cooling is intriguing to him. Dr. Studdart contacts a local company requesting a quote for the installation of a ground loop system. He is surprised when he finds how expensive it will be. The sales consultant explains that a ground coil requires considerable excavation and long lengths of piping.

Instead, the consultant suggests a very efficient air-source split-system heat pump with a SEER of 18 and an HSPF of 10. This is a much less costly alternative that still delivers impressive energy savings by using a

two-capacity compressor and ECM fan motors. Although it is not exactly what Dr. Studdart originally had in mind, it is certainly the most practical solution for his heating and cooling needs.

UNIT 63—REVIEW QUESTIONS

1. What type of heat pump is the most common, and why?
2. What is the relationship between air-to-air heat pump heating capacity and outside air temperature?
3. What is a dual-fuel heat pump?
4. What is the HSPF of the most efficient air-to-air heat pumps?
5. What are the efficiency requirements for the Energy Star label to be awarded for an air-to-air heat pump?
6. What are some advantages of the mini-split heat pump?
7. How should heat pump outdoor units be mounted in areas where snowfall accumulates?
8. What does the Y terminal on most heat pump thermostats control, and when is it energized?
9. Why do air-source heat pump thermostats have two stages of heat?
10. What is usually used for auxiliary heat?
11. What is the difference between auxiliary heat and emergency heat?
12. What is the purpose of the crankcase heater?
13. What two types of solar-assisted heat pump systems are available?
14. What are the two main types of defrost controls used on heat pumps today?
15. Describe what happens during the defrost cycle.
16. When describing a defrost control, what do the terms *initiation* and *termination* mean?
17. Why must a heat pump indoor coil be able to withstand higher pressures than a regular air-conditioning evaporator coil?
18. Where is the indoor coil in relation to the blower on a heat pump blower coil?
19. What is the system balance point?
20. What is the purpose of the outdoor air thermostat?
21. What determines which metering device is active?
22. Where in the airstream are electric strip heaters installed?
23. Describe the operation of a heat pump with electric strip heat operating below the balance point.
24. Describe the operation of a dual-fuel heat pump operating below the balance point.
25. What is the difference between demand defrost control and time temperature defrost control?
26. What are some of the advantages of an air-to-water heat pump system?
27. How does a heat pump hot-water heater work?
28. What is the difference between a mini-split system and a traditional split system?
29. What controls the operation of the furnace and heat pump in a dual-fuel system?

UNIT 64

Geothermal Heat Pumps

OBJECTIVES

After completing this unit, you will be able to:

1. describe the applications best suited for air-source and water-source heat pumps.
2. recommend the most efficient heat pump system depending on the application.
3. describe the different configurations for all of the major heat pump types.
4. explain why some heat pump systems are better suited than others depending on the geographical location.
5. list the advantages of air-to-water systems, mini-split systems, and water-source systems.

64.1 INTRODUCTION

Geothermal heat pump systems move heat from the earth into your house. They take advantage of the moderating effect of the earth on seasonal temperatures. Unlike the air temperature, which can change 30°F from day to night, earth temperatures take much longer to change. At depths below 28 feet, the earth temperature is nearly constant. Geothermal systems use buried loops in which water is circulated. Water-source heat pumps are used to extract heat from the water. Geothermal water-source heat pump systems are more efficient than air-source heat pumps because water is a more efficient heat-transfer medium, the temperatures they operate at are more moderate due to the moderating effect of the earth, they do not need a defrost cycle, and their capacity does not drop off as the temperature drops outside.

64.2 WATER-SOURCE HEAT PUMP SYSTEMS

The operating concept of a water-source heat pump is similar to an air source system: heat is transferred from one coil to another. Instead of two air coils, water-to-air heat pumps use one water coil and one air coil (Figure 64-1). In heating, water-source systems use water as their heat source and the indoor air as the heat sink. The water coil transfers heat from the water to the refrigerant, and the air coil transfers heat from the refrigerant to the air. In cooling, water-source systems use the indoor air as their heat source and the water as the heat sink. The air coil transfers heat from the air to the refrigerant, and the water coil transfers heat from the refrigerant to the water. The refrigeration cycle for a water-source heat pump is a little simpler because water-source units have a much narrower operating temperature range than air source units. The water-source unit's capacity is less variable because the water being supplied to it must be moderate in temperature. This means that water-source units do not require suction line accumulators or charge compensators. Also, most water-source packaged

Figure 64-1 Horizontal-style water-source heat pump with panels removed.

units use a single bi-flow thermostatic expansion valve, so there are no check valves or extra metering devices. Since the fluid circulating through the water-source unit cannot be allowed to freeze, this type of heat pump does not need a defrost cycle.

The water coil in a water-source unit is a coaxial tube in tube coil. These heat exchangers are made of copper, cupronickel, or stainless steel. Figure 64-2 shows a water-to-refrigerant coil and a cutaway of the coil. Water travels through the inner tube, and refrigerant flows through the outer tube. The water and refrigerant always travel in opposite directions. This counterflow design improves efficiency by placing the coldest water against the coldest refrigerant and the warmest water against the warmest refrigerant. The water coil should be located in the heated area to prevent possible freeze-up if the outdoor ambient temperature should drop below 32°F. If the

Figure 64-2 Cutaway view of a water coil.

water-to-refrigerant heat exchanger is part of a packaged unit, it would be located in the conditioned area.

Water-source systems can be connected to an open or closed water loop. Open loops are open to the air and are supplied with water from a well. The water for an open loop is not recirculated. Figure 64-3a shows a typical open-loop system. Closed loops are pressurized loops

of water buried in the ground that recirculate the same water. The water transfers heat between the ground and the refrigerant in the unit. Figure 64-3b shows a typical closed-loop system.

Closed-loop systems use much smaller water pumps than open-loop systems. A closed-loop pump only has to overcome the resistance of the loop; it does not have to work against gravity. Even in a vertical loop, the weight of the water flowing down balances the weight of the water being lifted, so gravity is not a factor. In an open loop, the pump must lift the water against gravity, so a much stronger pump is required.

Water-source packaged units are available as either vertical or horizontal discharge. Many water-source systems also have supplemental heat, but it is not as necessary for them because they do not lose capacity as the outdoor temperature drops and they do not have a defrost cycle. However, a unit sized correctly for cooling may still be undersized for heating and require additional heat.

64.3 WATER-TO-AIR PACKAGED SYSTEM

Packaged water-to-air heat pumps are the most popular type of water-source heat pumps. The building is heated by a forced-air duct-distribution system similar to that of an air-to-air system. However, there are some significant differences. The most notable is that the outdoor coil absorbs heat from a water source rather than the outside air (Figure 64-4; notice that domestic hot water heat can also be added to the system).

Whether using a shallow pond, well, or groundwater, the temperature remains fairly consistent and above freezing even as outside temperatures drop. Depending on latitude, ground temperatures range from 45°F to 75°F, so that any water below the ground-level frost line should be somewhere within this range. Because the outdoor coil never drops below freezing, it never needs to be defrosted.

With all water-source heat pumps, the compressor and refrigerant components can all be located inside the building (Figure 64-5). The packaged-unit water-to-air configurations can come as upflow, downflow, and horizontal

Figure 64-3 (a) Open-loop system; (b) closed-loop system.

Figure 64-4 Water-to-air cycle.

supply-air options with ECM variable-speed fan motors. Figure 64-6a shows a vertical water source unit and Figure 64-6b shows a horizontal water source unit.

64.4 WATER-TO-AIR SPLIT SYSTEM

Water-to-air heat pumps can also come as split systems. These are more common for retrofit applications where the outdoor coil can be replaced with the heat pump but

(a)

Figure 64-5 Water-source heat pump compressor can be located indoors.

(b)

Figure 64-6 (a) Vertical water-to-air packaged heat pump; (b) horizontal water-to-air packaged heat pump.

Figure 64-7 (a) Split water-to-air heat pump air-handler installation with outdoor compressor; (b) split water-to-air heat pump air-handler installation with indoor compressor.

the indoor air-handler wiring and configuration remain the same (Figure 64-7a). This type of system is popular if indoor space is limited and the air handler can be located in the most convenient location. A narrow closet may not be large enough for a packaged unit but may be perfectly suitable for an air handler. If space allows, the compressor section can also be located indoors (Figure 64-7b).

64.5 GEOTHERMAL HEAT PUMP SYSTEM

Geothermal systems are water-source heat pump systems whose heat source comes from the ground. This can either be water supplied directly from a well or water circulated in a loop buried in the ground. The most common geothermal systems are closed-loop systems with water circulated through

ground loops. The water acts as a secondary refrigerant, absorbing heat from the soil and transferring it to the refrigerant in the heat pump. This is less efficient than absorbing heat from groundwater, but it avoids many problems associated with open loops, such as mineral deposits in the water coil. The difference in efficiency can be offset by increasing the loop size, effectively making the heat exchanger larger.

Ground-source heat pumps are well suited for cold climates because the temperature of the earth below the frost line remains above freezing and relatively constant all year long. However, there are a number of factors to consider before recommending the installation of this type of system. The site must be evaluated with regard to geology, hydrology, and land availability. Extremely rocky soil or land on top of a rock outcropping may not be practical due to the expense in drilling or trenching. A large area of land is required for a horizontal installation—a half acre minimum for a small system. All soil does not transfer heat readily. Sandy, dry soil is a poor heat conductor, while moist clay is ideal. Although geothermal systems use less energy than most other forms of heating, they are also the most expensive to install.

A closed loop located in a body of water has the advantage of the natural circulation of water where the warm water rises and the cold water falls, allowing for heat transfer through convection. In contrast, a ground loop has a limited ability to remove heat from the ground. As the ground surrounding the loop grows colder, it will take time for additional heat to travel through the soil by conduction. It is therefore essential that a large enough area is excavated for the ground loop to be effective as a heat sink. Horizontal ground loops are the most economical but can take up a lot of space (Figure 64-8). Vertical ground loops take up less space but are more difficult to install, as they need to be drilled rather than dug with a backhoe or trenched with an excavator (Figure 64-9).

The soil and rock that make up the area to be used for the ground loop need to be considered. Difficulties can be encountered in areas with an abundance of hard rock with little soil available to trench. Ground surface water can sometimes be desirable for the ground loop as long as it does not interfere with the installation process. A trench that fills with water after it is dug and the piping has been installed will provide for better heat transfer. There will be some natural circulation of the ground water that will improve the ground-loop efficiency as long as the operating conditions are set so as not to freeze the water on the outer surface of the piping, which would then only reduce rather than increase heat transfer.

TECH TIP

A closed-loop ground system is practical only when the geology, hydrology, and land availability meet the requirements for the system to be installed. This type of system will have an extensive ground loop through which a secondary refrigerant circulates. Always check with all local codes and environmental regulations prior to installing this type of system. In some areas, any leakage of the secondary refrigerant from the ground loop into the soil could be deemed unacceptable and subject to a possible fine.

CLOSED LOOP SYSTEMS

64.6 GROUND-SOURCE HEAT PUMP CAPACITY

Although the capacity of a ground-source system does not fall off in cold weather like the capacity of an air-source system, it may not always be practical to size the unit to meet the entire heating demand in cold climates. Sizing to the heating load in a cold climate could oversize the system for cooling. Instead, the unit can be sized for the cooling load and supplemental heat added to make up the difference. The ground-source heat pump can be used in combination with gas, oil, or electric heat. Figure 64-10a shows an outdoor ground-source heat pump used in combination with a

Figure 64-9 (a) Vertical closed loop; (b) bored vertical closed loop.

furnace. Figure 64-10b shows a similar application but with the compressor located inside the building. The installation of a coil on an existing furnace may help to reduce energy costs. The ground-source heat pump will supplement the heat required for the building.

Another solution is to use a water-source heat pump that has a two-stage compressor. This way, the unit can be sized to meet the heating load when operated at high capacity. Then in cooling, operating at the lower capacity can keep the system from being grossly oversized. In a warm climate, the situation may be reversed. The higher capacity will meet the cooling needs and the lower capacity can allow extended run times and more efficient operation in mild winter weather.

64.7 WATER-TO-AIR OPEN-LOOP SYSTEM

An open-loop system is the simplest type of application for water-source heat pumps (Figure 64-11). Water is drawn from a well (Figure 64-12) and pumped through a refrigerant coaxial heat exchanger (Figure 64-13). In the heating cycle, heat will be absorbed from the water by the refrigerant. In the cooling cycle, heat will be given off to the water. Water-to-air heat pumps are more efficient than air-to-air heat pumps for two reasons: water is a better heat transfer medium than air, and the water temperature will remain fairly constant and not drop below freezing.

Figure 64-10a (a) Split ground-source heat pump add-on coil for fossil fuel furnace with outdoor compressor

Figure 64-10b (b) split ground-source heat pump add-on coil for fossil fuel furnace with indoor compressor.

Figure 64-11 Water-to-air packaged heat pump open-loop application.

TECH TIP

An open-loop system is practical only where there is an adequate supply of water and it is of good quality. Although the discharge water from the unit should not be contaminated, make sure that you check with all local codes and regulations regarding groundwater disposal.

OPEN LOOP SYSTEMS

Figure 64-12 Open-loop system. (Courtesy of Office of Energy Efficiency and Renewable Energy, U.S. Department of Energy)

Figure 64-13 Coaxial coil. (Climate Master, Inc.)

SERVICE TIP

The water coil in an open-loop system can lose efficiency over time because of scale deposits inside the water coil. The constant supply of new groundwater also delivers a constant supply of minerals that can settle in the heat exchanger. Keeping a clean water-inlet filter on machines in hard-water areas will prevent this. Once a coil is scaled, the unit will not operate efficiently, and it is very difficult to remove the scale.

Figure 64-14 Pond closed-loop system. (Courtesy of Office of Energy Efficiency and Renewable Energy, U.S. Department of Energy)

64.8 WATER-TO-AIR CLOSED-LOOP SYSTEM

A closed-loop system involves indirect heat exchange, unlike an open-loop system. This type of system is suitable where a pond or lake is located fairly close to the building (Figure 64-14). Most pond and lake water would not be suitable for an open-loop system because it contains too many minerals and contaminants that would lead to scale buildup inside the direct expansion evaporator coil. This type of system requires a secondary refrigerant, normally water or a water and antifreeze mixture. The closed loop is buried in the ground or sunk in a pond, and the water is circulated through this loop to the heat pump. Heat is transferred from the ground or pond to the secondary refrigerant in the loop, and the secondary refrigerant transfers the heat to the heat pump through its water-to-air coil.

Minimum pond sizes are roughly $\frac{1}{2}$ acre with at least an 8–10 ft depth. Coiled piping, typically polyethylene, is placed below the expected ice cap level in a series of loops or coils to increase the total surface area exposed to the water (Figure 64-15). A secondary refrigerant must be circulated through the piping to absorb heat from the pond water. Generally, an antifreeze solution with varying percentages of propylene glycol, methanol, or ethanol is used.

The reason for the use of antifreeze is primarily one of heat transfer. The secondary refrigerant must be at a lower temperature than the pond water for heat transfer to occur. The greater the temperature difference, the better the heat transfer. In a direct expansion system, the primary refrigerant evaporates and expands, absorbing both sensible and latent heat. In contrast, a secondary refrigerant does not evaporate and therefore only absorbs sensible heat, which makes the temperature difference and surface

Figure 64-15 Piping arrangements for pond closed loop.

area requirements greater than those needed for a direct expansion system.

As an example, assume the pond water temperature to be 40°F during the winter. The antifreeze temperature must be close to or slightly below the freezing temperature of water for good heat transfer to take place. If only pure, clean, distilled water were used as a secondary refrigerant, then there is the likely possibility for it to freeze. The use of antifreeze as a secondary refrigerant, however, does not necessarily suggest that the piping surface temperature of the pond loop could be lowered below freezing. If this were the case, then the pond water on the outside surface of the closed-loop piping would freeze and act as insulation, reducing the efficiency of the system dramatically. Due to the heat transfer through the piping and the flow velocity of the secondary refrigerant, its temperature might be at or slightly below freezing, while the outside surface temperature of the piping would still remain just above freezing. This type of system requires close control of the secondary refrigerant loop temperature to operate properly and efficiently.

In a water-to-air open-loop system, the heat from the water source is directly absorbed by the primary refrigerant and transferred to the air supply for the building. With a water-to-air closed-loop system, the heat from the water source must first be absorbed by the secondary refrigerant, which must then be absorbed by the primary refrigerant before being transferred to the air supply for the building. Therefore, in general, water-to-air open-loop systems will be less complex and more efficient than water-to-air closed-loop systems. However, the open loop will require more pumping horsepower than the closed loop. Both of these systems have efficiency and operating advantages when compared with air-to-air systems that operate in cold climates. An air-source heat pump must operate at higher compression ratios than water-source units because the air temperature is much colder than the groundwater temperature.

TECH TIP

Local codes and regulations must be checked carefully before installing a closed-loop pond system. There may be restrictions with regard to the type of secondary refrigerants that can be used because there is always a potential for leakage from a damaged pipe into the pond water. Another consideration often overlooked is the thermal shock to the natural pond environment. Changing the water temperature can change the type of plants and animals that can live in and around the water. There are many regulations today dealing with acceptable levels and restrictions on thermal pollution.

64.9 WATER-TO-WATER HEAT PUMP SYSTEM

Water-to-water systems use water as both the heat source and heat sink. They use two water coils and no air coils and are very compact units. Water-to-water heat pumps take heat out of the geothermal ground loop and transfer it to the water in a large insulated tank called a buffer tank. The buffer tank smooths out, or buffers, the effect of changing heat loads. The buffer tank allows the system to store heat, so that the amount of heat going into and out of the tank does not have to be exactly the same at all times. Water-to-water heat pumps are used with radiant floor-heating systems. Radiant floor-heating systems circulate hot water through tubing in the floor. Because radiant systems heat objects directly, they can provide comfort at lower room temperatures. Water-to-water heat pumps take heat out of the geothermal ground loop and transfer it to the buffer tank, and from the buffer tank to the water circulating in the floor (Figure 64-16).

If the heat pump capacity is insufficient for all of the heating needs, this type of system can be used in combination with an oil, gas, or electric furnace. If hot water for heating and chilled water for cooling are required, two separate buffer tanks may be used.

There are several advantages of radiant floor systems. Water transfers heat better than air. The amount of heat that can be carried by water in a small-diameter length of piping will be equal to or greater than the same amount that can be carried with the air in a large duct, thereby saving space. More power would be used to circulate an equivalent amount of air required for heating as compared to water. Radiant floor systems provide heat at the floor level, heating objects in the space and not the air directly. Less of the heat will be wasted by rising as hot air to collect at the top of the ceiling, which reduces efficiency.

A reversible water-to-water heat pump can provide chilled water to cool the building and hot water for the heating system. This type of system is in some ways similar to the air-to-water heat pump configuration. The basic cycle for a water-to-water heat pump consists of absorbing heat from a water source through an open- or closed-loop system and rejecting this heat to a buffer tank. The water from the buffer tank can be used with radiant flooring or hot-water baseboard heaters and in applications for melting ice.

64.10 WATER-TO-WATER HEAT PUMP EFFICIENCIES

Water-source heat pump efficiencies are often best determined by the coefficient of performance (COP). This can be seen from the water-to-water performance data from Table 64-1. The source EWT (entering water temperature) will have the most effect on the system performance. This is similar to the effect the outdoor air temperature has on air-to-air systems. However, as noted earlier, the water source will generally have a fairly constant temperature so that performance is more consistent over the entire heating season.

The load EWT and LWT are the temperatures of the water entering and leaving the heat pump to be circulated through the heating loop (radiant floor, baseboard, etc.). The water leaving the heat pump is at a higher temperature (LWT) as it enters the heating loop and comes back to the heat pump at a lower temperature after giving off heat to the space. Notice that the COP decreases as the required hot-water temperature for the heating loop rises. It would be more efficient to maintain a radiant floor temperature from between 80°F to 100°F, which generally should be sufficient. However, many hot-water baseboard heating systems require water temperatures of at least 120°F.

Also, notice that the COP increases at higher flow rates. Therefore, careful consideration should be given to the piping system layout and circulating pump requirements when sizing an appropriate system.

64.11 DOMESTIC HOT WATER

The hot discharge gas leaving the compressor is hot enough to heat domestic hot water. The condenser saturation temperature is typically too low to provide hot water, so all the hot-water heating is done from the discharge gas superheat. Many water-source heat pump systems can be configured to supply hot domestic water using de-superheating coils and water-circulating pumps built into the system (Figure 64-17). During cooling, the heat removed from the house is being wasted. Putting it in the hot water not only makes the heat pump more efficient by keeping the loop cooler, but it reduces the energy required to heat the hot water by using waste heat. In heating, the heat is not free, but it is still far more efficient than operating an electric hot-water heater. Water temperatures leaving the water-heating loop are generally no higher than 145°F.

Domestic hot-water heating can be configured with outdoor split systems (Figure 64-18) and indoor package units. Water-source heat pumps typically use an indirect water-to-water heat exchanger. This coil located inside the tank isolates the domestic (potable) water from the heating water. Some units have electric resistance heating elements for use as a backup.

Figure 64-17 Circulating pump and connections for domestic hot-water heating.

Figure 64-18 Domestic hot-water split system with outside compressor.

UNIT 64—SUMMARY

A geothermal heat pump system is the least expensive way to heat. Geothermal systems circulate water through closed loops buried in the ground to transfer heat from the ground into the house using a water-source heat pump. Geothermal systems do not lose capacity as the air temperature drops because they extract heat from the ground, which is a stable temperature. Water-source systems are more efficient than air-source systems because water is a more efficient heat-transfer medium, the temperatures they operate at are more moderate due to the moderating effect of the earth, they do not need a defrost cycle, and their capacity does not drop off as the temperature drops outside. Water-source units can be connected to either open or closed loops. An open loop does not recirculate the water. Closed loops recirculate water in closed loops buried in the ground or in the bottom of a large body of water. Loops can be horizontal or vertical. Water-to-water systems can be used to provide warm water for radiant heating systems. Some water-source systems have de-superheating coils and circulating pumps to provide domestic hot water as well as space heating and cooling.

WORK ORDERS

Service Ticket 6401

Customer Complaint: Low Water Temperature

Equipment Type: Water-Source Heat Pump with Open Loop

The customer complains to the technician that the heat from the radiant floor is not sufficient. Dial thermometers were installed in the lines leaving the heat pump

and the customer notes that the water temperature has been gradually decreasing since the system was installed more than a year ago.

Having never been to this residence before, the technician begins to review the specifications for the system. The technician is surprised to find that the system is operating with an open loop from a small man-made pond located in the backyard. The water quality is obviously poor and no doubt has led to scale and deposits on the water side of the refrigeration coil. This would reduce the heat transfer and lead to a gradual decrease in amount of heat absorbed from the pond water. The technician also finds that the auxiliary electric heat for the buffer tank is disconnected.

The customer explains that during the initial installation, the contractor recommended a closed loop, but it was going to be much more expensive to install. It was the customer's decision to go with the open loop. A few months ago, when the auxiliary electric heat began running a majority of the time, the customer simply disconnected it.

The technician explains that it is not worthwhile to try to cut costs by trying to change the parameters for the application involved. It does no good to try to save a few dollars on the installation to only have a system that does not work properly. The technician politely tells the customer that the technician is only willing to work on the system if the customer follows the suggestions for improvement. At the very least, a closed-loop system needs to be put into place if the existing system is to be used.

Service Ticket 6402

Customer Request: New Installation

Equipment: Water-Source Heat Pump

Big Lake Power and Light is building a new office building that they would like to make a showcase for innovative energy-conservation measures. A sales consultant is called in to help them decide which type of system would work best. The building is fairly large and there are a large number of different spaces. The best way to configure the space would be to set up a number of different heating zones.

The building is located in a rather cool climate, which would certainly have an adverse effect on the efficiency of any heat pump system. However, the site is adjacent to a large lake, which would allow for water-source heat pumps connected together on a closed-loop system. The lake water temperature at the location of the coils would remain fairly constant and provide enough heat for the building. In terms of energy conservation, this is exactly what the customer had in mind.

Service Ticket 6403

Customer Request: New Installation

Equipment Type: Water-to-Water Heat Pump

Tiles R Us is building a showroom to show off some of their tile floor products. They want to use radiant floor heating because they do not want the customers to perceive the flooring as cold. One method suggested by the sales consultant would be to use an LP gas-fired hydronic system. This would be the least complicated system for them to install. However, the owner of the showroom is concerned about rising energy costs and would like to take advantage of heat pump energy savings if possible.

The sales consultant notices that space for a geothermal application is limited. However, a vertical loop, which would reduce the amount of area that is disturbed when the loop is installed, would probably work. The consultant would need to perform some additional calculations to make sure. The sales consultant recommends a water-to-water geothermal heat pump application but cautions that he needs to make sure the loop sizing would work for a vertical system at the site. The heat pump system would still provide warm water for a warm floor, and the heat pump would provide operating savings over the gas boiler. The initial installation cost will be greater, so this would need to be calculated against the annual fuel savings to see if the decision would make economic sense.

UNIT 64—REVIEW QUESTIONS

1. What is the difference between a water-source heat pump and an air-source heat pump?
2. What type of metering device do most packaged water-source heat pumps use?
3. Why do the refrigerant and water travel in opposite directions through the water coil?
4. Why don't water-source systems have a defrost cycle?
5. Explain the difference between an open loop and a closed loop.
6. What is a geothermal heat pump system?
7. What site conditions should be taken into account when considering the installation of a ground-source heat pump?
8. What is a water-to-water heat pump?
9. What are some of the advantages of radiant floor heating?
10. Why are the insulated water tanks for heat pump systems referred to as "buffer" tanks?
11. Where is the compressor located in most water-source systems?
12. Why do geothermal heat pump systems work better in cold climates than air-source systems?

13. How can heat be considered a form of pollution?
14. How is heat transferred in a heat pump ground loop?
15. What type of system requires a secondary refrigerant?
16. What happens if water freezes on the outside of a closed-loop pond heat pump system?
17. What is the difference between the way a secondary refrigerant absorbs heat and the way a primary, direct expansion refrigerant absorbs heat?
18. Why would a water source heat pump be more efficient than an air-to-air heat pump?
19. What is the problem with sizing a geothermal heat pump to the full heat loss of a home in a cold climate?
20. What is the advantage of a dual-capacity compressor in a water-source heat pump?
21. How can water-source heat pumps help reduce domestic hot-water cost?
22. Which type of system requires more pumping horsepower for the water: open loop or closed loop?
23. What is most often used as a secondary refrigerant in geothermal systems?

UNIT 65

Heat Pump Installation

OBJECTIVES

After completing this unit, you will be able to:

1. discuss the decisions involved in selecting an air-source heat pump.
2. discuss the decisions involved in selecting a water-source heat pump.
3. plot a system balance point.
4. discuss the correct way to run the condensate drain lines in an attic installation.
5. calculate the correct refrigerant charge for a split-system heat pump.
6. list the types of water loops for water-source heat pumps.
7. list the steps for filling a ground-loop system for the first time.
8. discuss the process of checking water-source system performance.

65.1 INTRODUCTION

Heat pump systems lead all other forms of heat in terms of efficiency and low operating cost. The demand for heat pumps has increased because of the dramatic increase in the cost of all forms of energy. They must be installed correctly to take advantage of their energy-saving technology. The least efficient system installed correctly will outperform a more efficient system that is poorly installed.

Correct installation starts with selecting a system that meets the job's application requirements. This includes choosing a configuration, sizing the equipment, and sizing the auxiliary heat. Reading and following the manufacturer's installation instructions is the single most important step any installer can take. Attention to detail in locating the unit, refrigerant piping, wiring, duct connection, airflow, and water flow will pay dividends for the customer in the form of efficient operation and long equipment life.

65.2 EQUIPMENT SELECTION

Four decisions are involved in choosing a heat pump system:

- Air source versus water source
- Equipment configuration
- Equipment size
- Supplemental heat source

Air Versus Water

The first decision to make when selecting a heat pump system is to use either an air-source unit or a water-source unit. Air-source systems have a lower installed cost, while water-source systems usually have a lower operating cost. The decision is primarily an economic one: how much money is available to invest versus how long it will take to recover the investment. A water-source system will require either an abundant supply of water or installation of a ground loop for recirculation of the water.

Configuration

The type of building construction and the location of the unit helps determine the best configuration for any particular job. Buildings on slabs almost always have the ductwork in the attic. Horizontal split systems located in the attic are frequently used on this type of construction. Upflow split systems can be used if the air handler is located in a closet. For houses on a foundation with a crawlspace, side-discharge packaged units are popular. The unit sits on the end of the house and the duct runs in the crawlspace. Horizontal split systems are also popular for crawlspace construction. A downflow unit in a closet can be used with crawlspace construction, but this is less common. Buildings with basements usually have upflow systems with both the system and the ductwork located in the basement. Table 65-1 shows typical applications for several types of units.

Table 65-1 Typical Heat Pump Applications

Source	Type of Unit	Application
Air	Bottom-discharge packaged	Rooftop mounted on curb
Air	Wall-mount packaged	Schools mounted on outside wall
Air	Split system	House with blower in attic, crawlspace, or basement
Water	Vertical-discharge packaged	Unit located in basement or closet
Water	Horizontal discharge	Unit located above dropped ceiling

Equipment Size

The challenge in sizing a heat pump is matching both the cooling and heating load of the structure, which are usually not the same. Meeting the building heat loss with the heat pump alone is difficult because the heating capacity of the heat pump declines as the heat loss of the building increases. In most cases, a heat pump sized to meet the heat loss at the winter design temperature listed in the ACCA Manual J would be grossly oversized in cooling. Systems that are grossly oversized in cooling are very energy inefficient, increasing the cost of operation. They also do a poor job of controlling humidity because they do not operate long enough to remove much moisture. In severe cases, this can contribute to mold and mildew formation in the structure.

The most common practice in sizing heat pumps is to size the system for the cooling load and add supplemental heat to make up the difference in heating. Some engineers will select a unit with a cooling capacity of a half ton larger than necessary to help increase the heating capacity without causing significant problems in cooling operation.

Two-stage heat pumps are now being offered that help address the issue of sizing. These systems use compressors with two pumping capacities (Figure 65-1).

These systems can be sized by matching the cooling load to the low-capacity cooling. The compressor runs at low capacity most of the time, allowing efficient operation

Figure 65-1 Two-capacity compressor.

and dehumidification. The system can operate at full capacity when more capacity is needed, such as at lower ambient temperatures in heating.

Determining the Balance Point

The heat loss of the building and the capacity of the equipment determine a system's balance point. This means that the balance point for a 2-ton brand X heat pump would be different for your house than your neighbor's house. It also means that the balance point for a 2-ton brand Y heat pump could be different from a 2-ton brand X heat pump, even on the same house! When selecting equipment, it is useful to plot the balance point of the systems being considered. To calculate a balance point correctly, you need the following:

- A heat load calculation for the specific house
- The capacity ratings for the specific model unit you propose to use—two rating points are necessary; usually this will be at 47°F and 17°F
- A piece of graph paper and a straightedge or a balance point graph

First, plot the structure heat loss. Mark a point on the graph that represents the heat loss at the Manual J winter design condition. Mark another point along the bottom of the graph to represent 0 BTU heat loss at 65°F. Draw a straight line between these two points. This line represents the building load.

To plot the equipment capacity line, mark a point that represents the equipment capacity at 47°F and another that represents the equipment capacity at 17°F and draw a straight line through them. This is the equipment capacity line. The point at which the equipment capacity line intersects the structure load line is the balance point. To find this temperature, read straight down from the intersection of the two lines. Figure 65-2 shows a balance point graph for a house with a heat loss of 45,000 BTU/hr at 18°F and a heat pump with heating capacities of 35,000 BTU/hr at 47°F and 20,000 BTU/hr at 17°F. At the balance point of 32°F, the heat loss is 29,000 BTU/hr.

Figure 65-2 Balance point graph.

Supplemental Heat

Auxiliary heat will be required for temperatures below the balance point. The most common form of auxiliary heat is electrical strip heat. This has the advantage of being relatively inexpensive, easy to control, and easy to install. The overall efficiency of the heat pump is reduced anytime the strips are operated. Outdoor thermostats are often used to avoid operating this form of heat whenever the ambient temperature is above the balance point. This is why establishing the system balance point is important. The goal is to deliver comfort at the most reasonable operating cost possible. In practice, the outdoor thermostat is set 5°F above the actual system balance point to ensure that the equipment can keep up with the load.

The next decision is to determine how much auxiliary heat is needed. One possible solution is to add enough auxiliary heat to make up the difference between the building load and the equipment capacity. This would be considered the absolute minimum amount of auxiliary heat, since anything less would leave the customer without sufficient capacity at cold temperatures. The only problem with this approach is that it assumes the heat pump capacity will always be available. If any problems occurred in the refrigeration system, the customer would be left without adequate heating capacity. If this is a concern, the auxiliary heat can be sized to meet the entire load at the design condition.

Auxiliary heat does not have to be electric strip heat; it can also be a fossil fuel furnace. Heat pump systems installed with fossil fuel auxiliary heat are called dual-fuel systems. Typically, these systems take advantage of the heat pump's capacity to deliver economical heat at mild temperatures and the furnace's capacity to deliver large amounts of heat with no capacity loss at low temperatures.

65.3 AIR-SOURCE SYSTEMS

Steps involved in installing an air-source heat pump are as follows:

- Locate the equipment.
- Connect the ductwork.
- Size and connect the power wiring.
- Wire the controls.
- Connect the refrigerant lines.
- Evacuate and charge the system.

Outdoor Unit Location

Ideally, heat pumps should keep the house comfortable without being noticed. All equipment should be located where sound from the equipment will not be a nuisance, away from bedroom windows and outdoor patios. It is also important that the equipment is not unsightly to the homeowner. The front of most houses is usually off limits. In many places the outdoor equipment is located on the side or back of the house. However, in areas with little or no yard, equipment is often located on the roof. In Georgia, locating a unit on someone's roof is considered abominable. However, in Arizona, where swamp coolers are common, locating equipment on the roof is normal.

Figure 65-3 Condensing unit elevated above pad.

Packaged units and split-system condensing units should be located above the average winter snow line. In Florida, the unit can rest directly on the pad, while in Michigan, the unit should be elevated several feet above the ground (Figure 65-3). Systems buried in snow will not work well.

Airflow should be considered when locating the equipment. Vertical discharge units should not be located under a deck or overhang. Horizontal discharge units should not be located with their discharge air blowing directly into a wall. The amount of space required around a unit to ensure proper airflow is listed in the installation instructions.

Indoor Unit Location

Both air- and water-source heat pumps can be split systems. The indoor blower coils for a split system may be located in a basement, closet, crawlspace, or attic. When installed in the attic, the unit should not rest directly on the ceiling joists or on plywood on top of the ceiling joists because fan noise and vibration will be transmitted into the house through the ceiling. To avoid unwanted sound transmission, the blower coil may sit on vibration isolation pads or be suspended from the roof rafters as long as the rafters will support the weight. It should be noted that this is generally not allowed on most trussed roof systems.

Indoor Unit Configuration

Many heat pump air handlers can be installed in the up-flow, downflow, or horizontal position. However, this is not simply a matter of flipping the unit on its side. The installer

must read and follow the installation instructions carefully. Frequently, parts of the unit will need to be repositioned to change the orientation of the air handler. The installer must make sure of the following:

- The coil orientation in the cabinet is correct for the position of the unit.
- The drain pan is positioned under the coil.
- The correct drain opening is being used.
- The service access panel has enough clearance to service the unit.

Drain Connections

When the unit operates in cooling, the indoor coil creates condensate water that needs to be drained. The drain should be at least $\frac{3}{4}$ -in PVC and should slope downward at least 1/8 inch per foot. The air velocity rushing past the drain hole creates a vacuum that can hold the water in the drain pan. Figure 65-4 shows water standing in the drain of an operating unit with the drain line removed.

The drain is normally trapped to keep this from happening. The water in the trap stops air from coming up the drain line and allows the water in the drain pan to drain out. Some units have traps built into the unit; these should not be trapped. The installation instructions will specify whether to trap the drain (Figure 65-5).

Units installed in the attic should have an auxiliary drain pan under them that is larger than the overall dimensions of the unit (Figure 65-6).

The purpose of the auxiliary drain is to prevent damage to the ceiling when the main drain clogs. The auxiliary drain opening in the unit should be run to the auxiliary drain pan. The drain line from the auxiliary pan should be run out separately from the main drain; the two drain lines should not be tied together. The auxiliary drain should exit in a location

Figure 65-4 Standing water in a drain outlet.

Figure 65-5 Drain trap.

Figure 65-6 Drain pan under an attic unit.

where the water will be obvious to encourage investigation of the source of the water (Figure 65-7). Float switches can be installed to shut the unit down in the event the drain becomes plugged. The increasing water level will cause the float to rise and activate the shutoff switch.

Units installed in basements and crawlspaces usually require a condensate pump (Figure 65-8).

The water drains into the condensate pump sump and the condensate pump pumps the water out when the sump fills. Small $\frac{3}{8}$ -in inside diameter plastic tubing runs from the condensate pump outside. This line should have a check valve to prevent water from flowing back into the sump when the pump shuts down. Figure 65-9 shows a system connected to a condensate pump. A float activated shutoff switch can also be installed on this type of system.

Connecting the Ductwork

Metal ductwork may be fastened directly to the $\frac{3}{4}$ -in flanges of the blower coil (Figure 65-10).

Sheet-metal screws are used to fasten the ductwork to the flanges. Fiber ductboard should not be connected

Figure 65-7 Drain outlet.**Figure 65-8** Condensate pump.

directly to these flanges. A metal collar at least 3 in wide should be attached to the flanges first before attaching fiber ductboard. The metal collar is attached to the flanges with sheet-metal screws and the fiber duct is connected to the collar using long sheet-metal screws with large washers under the heads.

General Power Wiring Requirements

The type of wire that may be used is listed in the installation instructions and frequently also on the unit. If aluminum wiring is used, the installer must check to see if the connections on the unit are designed for aluminum conductors. Using aluminum conductors on units that do not have aluminum rated connections will void the system warranty! Aluminum conductors also require application of antioxidant paste on the connection to prevent poor connection as a result of oxidation (Figure 65-11).

The conductor should be sized using the wire sizing tables of the National Electric Code to handle the minimum circuit ampacity listed on the unit data plate or installation instructions. The disconnect should be located within sight of the equipment and rated no smaller than 115 percent of this minimum circuit ampacity. The overcurrent protection

**Figure 65-9** Installed condensate pump. (Courtesy of InspectAPedia.com)**Figure 65-10** Metal duct connected to flanges with sheet-metal screws.

Figure 65-11 Antioxidation paste. (Courtesy of IDEAL Industries, Inc.)

should be no larger than the maximum overcurrent protection listed on the data plate or installation instructions. All wiring should pass through strain-relief connectors whenever it passes through the cabinet or disconnect.

Power Wiring for Packaged Units

Supplemental electric heat strips are sized for each job and are added in the field. Because the electric specifications will vary depending upon which heat kit is being installed, the installation instructions list specifications for many different combinations of units and heat kits. The installer must identify the data for the particular unit and heat kit being installed.

Power Wiring for Split Systems

Split systems require two power circuits: one for the indoor blower and one for the outdoor condensing unit. Each should have its own disconnect and overcurrent protection. The electrical data for the circuit to the indoor blower must be selected from a list of data because the supplemental heat is sized for each job and installed in the field.

Control Wiring

All control wiring should be solid copper and at least 18 gauge. Control wires are typically bundled together in groups

Figure 65-12 Thermostat wire bundle.

of wires with different colors (Figure 65-12). Heat pump controls require anywhere from four wires per bundle for digital controls like the Carrier Infinity system, to 10-wire bundles for some multistage systems using traditional controls.

Packaged Unit Control Wiring

The control wiring for packaged units is straightforward: there is one bundle of control wires from the thermostat to the unit. The control wiring connects to the thermostat sub-base terminals on one end and to the unit terminal board on the other end. The ends of the control wires should only be stripped far enough to fit completely in the terminal; bare wire should not be hanging out beyond the connection points (Figure 65-13).

The installation instructions will identify which terminals on the thermostat should be connected to which

Figure 65-13 Right and wrong ways to strip and connect thermostat wire.

Figure 65-14 Control wire pigtails.

terminals on the unit. The majority of manufacturers keep it simple by using the same letters on the thermostat and the unit. Some manufacturers do not use a terminal board on the unit; they have color-coded control wire pigtails instead. The control wires from the thermostat are connected to these using wire nuts (Figure 65-14).

Split-System Control Wiring

Split systems require one wire bundle running from the thermostat to the indoor unit and another running from the indoor unit to the outdoor unit. Some of the wires in these bundles perform the same function in each bundle, but other wires in the bundles have functions that are only

necessary for the indoor or outdoor unit. Manufacturers try to simplify this by using common terminal designations, but it is not possible to wire most split-system heat pumps by just connecting all the same color wires together. Table 65-2 shows common terminal designations used in the industry. While it is useful to know the most common control wire letter designations, installers should always refer to the installation instructions when wiring a system.

CAUTION

Note that the green wire in the indoor bundle is used to energize the fan and is not needed in the outside bundle. Many installers use the green wire in the outside bundle for the common connection. If green is used for common in the outside bundle, connecting the green wires of the two bundles together will short out the transformer when the fan is energized.

CAUTION

Note that there are two definitions of the B terminal. On most over-the-counter thermostats, B is connected to the red power terminal whenever the thermostat is set to heat. Heat pumps that energize the reversing valve in heat use this terminal. Some manufacturers use the B terminal for the common side of 24 V. If the B terminal of an over-the-counter thermostat is connected to the B terminal on a unit that uses B for common, the transformer will short out when the system is placed in heat.

Table 65-2 Common Industry Terminal Designations

Thermostat			Indoor Unit			Outdoor Unit	
Terminal	Function	Wire	Terminal	Function	Wire	Terminal	Function
R	24 V power in	Red	R	24 V power out	Red	R	24 V power in
Y	Energize contactor	Yellow	Y	None	Yellow	Y	Energize contactor
O	Energize reversing valve in cooling	orange	O	None	Orange	O	Energize reversing valve in cooling
B	Energize reversing valve in heating	Blue	B	None	Blue	B	Energize reversing valve in heating
B	Common side of 24 V	Blue	B	Common 24 V out	Blue	B	Common 24 V in
C	Common side of 24 V	Installer's choice	C	Common 24 V out	Installer's choice	C	Common 24 V in
G	Fan	Green	G	Energize fan	None	None	None
W	Energize aux heat	White	W	Energize aux heat	white	W	Energize aux heat
W2	Energize aux heat	White	W2	Energize aux heat	white	W2	Energize aux heat

Figure 65-15 Dual-fuel board.

Control Wiring for Dual-Fuel Heat Pumps

When a fossil fuel furnace is used for the auxiliary heat, a separate control board is added to coordinate the operation of the furnace and heat pump (Figure 65-15).

These systems use three wire bundles:

1. Thermostat to the dual-fuel board
2. Dual-fuel board to the furnace
3. Dual-fuel board to the heat pump

Because the wiring for these is considerably more complex than traditional split systems, it is imperative that the installer read all the instructions and follow the wiring diagram.

Infinity Control Systems

Carrier products offer systems with a digital control system. All components wire with exactly four wires. Two wires provide the control power and two more are the communication wires. These systems use serial communication to control all pieces of equipment in the system. Installation is greatly simplified because everything is wired with the same four wires (Figure 65-16).

Figure 65-17 Split-system refrigerant line set.

Running Refrigerant Lines

Split-system heat pumps require two refrigerant lines running between the indoor and outdoor units: a large gas line and a smaller liquid line. The lines can be connected to the units by brazed joints, flare fittings, or compression fittings. The connection method is determined by the stub-outs on the equipment. The lines are typically sold in line sets with insulation already on the gas line (Figure 65-17).

Line sets are made of soft ACR copper tubing. ACR tubing is type L copper tubing that has been dehydrated. The insulation used on the gas line of a heat pump must be able to withstand high temperatures. Before using any insulation on a heat pump gas line, check to be sure it is rated for heat pump duty.

SAFETY TIP

Never use plumbing copper to run refrigeration lines! Standard plumbing copper is type M, which has a thinner wall than type L copper used in ACR tubing. Plumbing tubing is also not dehydrated, so the risk of introducing moisture into the system is increased.

Most manufacturers limit the line length on residential systems to 150 ft. Long lines have increased pressure drop, lowering system efficiency. This can be offset by increasing the size of the lines. However, manufacturers differ in philosophy on line sizing for residential systems. At least one major manufacturer does not want the line size increased from the stub-outs on the equipment. Other manufacturers recommend increasing the line size to offset length and provide charts to determine the correct line size. Either way, the best practice is to keep lines as short as possible and follow the manufacturer's instructions.

Figure 65-18 Cooling valves while brazing.

TECH TIP

One change most manufacturers made to increase the efficiency of their systems was increasing the size of the suction line on most residential systems. Suction lines as small as $\frac{5}{8}$ in outside diameter (OD) were common at one time on 2-ton systems. Today most 2-ton units use $\frac{3}{4}$ -in or even $\frac{7}{8}$ -in suction lines. This increases the efficiency by reducing the pressure drop in the suction line.

Connecting Brazed Lines

For units with brazed connections, pull back the insulation on the gas line before brazing to avoid burning the insulation. To protect the rubber O-rings in the valves, cool the installation valves with thermal absorbing paste or wet rags during brazing (Figure 65-18).

Connecting Compression Lines

Manufacturers used to offer equipment with compression fittings for the stub outs. The copper tubing should be straight and clean where the ferrule slides over it and goes into the compression fitting. Any dents in the tubing or grit under the ferrule will cause a leak. Make sure the tubing is seated fully into the fitting before tightening. Once the ferrule starts to compress, it cannot be moved. Mistakes must be cut off and a new attempt made with a new ferrule. Only use compression fittings supplied by the air conditioning manufacturer. Never try to use plumbing fittings on refrigeration systems.

Evacuation and Charging

Packaged units do not need to be evacuated and charged; they arrive from the factory with the correct charge. Split systems also are shipped with a refrigerant charge, but they usually do require some adjustment to the refrigerant charge to account for their refrigerant lines. Most manufacturers ship their condensing units with enough charge for the outdoor unit, the indoor coil, and some assumed length

Figure 65-19 Split-system shutoff valves.

of refrigerant line. This charge is held in the condensing unit with split system shutoff valves (Figure 65-19).

These valves are front-seated when the unit is shipped. The Schrader access fittings on these valves are always open to the refrigerant line regardless of the valve’s position. The shutoff valves are opened only after the following steps are complete:

- Installing the lines and coil
- Leak testing the lines and coil
- Evacuating the lines and coil

Leak Testing

The lines and coil should be leak tested with dry nitrogen. Nitrogen makes a good initial leak test gas because it is inexpensive and legal to release to the air. Pressurize the lines and coil to between 100 psig and the system’s low-side test pressure. Make a note of the time and pressure. Use soap bubbles or an ultrasonic leak detector to check the line connections at both the inside and outside units. Also, check any other mechanical or brazed joints in between. Finally, if the unit uses a field-installed expansion valve, check all connections on the expansion valve. After making all these checks, recheck the pressure. The system has passed the initial leak test if the pressure is the same as when the system was first pressurized.

Evacuation

Release the nitrogen to the air and connect a vacuum pump and vacuum gauge. Evacuate the lines and coil until you reach a vacuum level below 500 microns. Shut the valve off at the vacuum pump and wait to see if the vacuum holds. A rise of 100–200 microns is normal. If the vacuum holds, the system has passed its second leak test.

Adjusting the Charge

It is now time to open the installation valves. Opening the valves allows the refrigerant that is trapped in the condenser to travel throughout the system. If the actual line length is exactly the same as the manufacturer’s assumed line length, you are done. If the lines are longer than the assumed length, you will need to add refrigerant. If the lines are shorter, you will need to remove refrigerant. The amount of assumed line length varies from 15 to 30 ft depending upon the manufacturer. Many systems now include information on the unit that lists the assumed line length and gives the required per-foot charge adjustment. Table 65-3 shows the allowance per foot for different liquid line sizes. No allowance is made for the vapor line.

Digital scales are often used for measuring the refrigerant charge. Most are battery operated and can be zeroed in to count up or down. To do this, place the refrigerant cylinder securely on the scale, making sure that it is fairly level and not rocking. This type of scale is very sensitive, and just a little motion can lead to a false reading. Once the cylinder is in place and the system is ready to charge, zero the scale with the scale control panel. As the refrigerant leaves the cylinder, the amount of weight change will be indicated as a negative number.

65.4 WATER-SOURCE SYSTEMS

The first decision to make when planning a water-source installation is where the water will come from. Water-source heat pumps use lots of water, up to 4 gallons per minute per ton. Typically, the water is either supplied from a deep well or is recirculated in a ground loop.

CAUTION

Do not overtighten the installation valves when opening them. Stop turning the valve as soon as you feel increased resistance or see the top of the plug. A lock ring is all that keeps the valve plug in. Overtightening it in the counter-clockwise direction will result in the valve plug shooting out at a pressure exceeding 100 psig, and all of the refrigerant will come with it! This would be a physical danger to the technician. There could also be possible damage to the unit.

Table 65-3 Charge Allowance Adjustment per Foot for Different Liquid Line Sizes

Liquid Line Size	Ounces per Foot
¼ in OD	0.3 oz
5⁄15 in OD	0.4 oz
3⁄8 in OD	0.6 oz
½ in OD	1.2 oz

Types of Water Loops

There are many variations on ground loops, including the following:

- Open
- Horizontal loops
- Vertical loops
- Slinky loops
- Lake loops

Open Loops

The open loop draws water from a well and deposits the water in another well or in nearby surface water. Wells for open loops must be deep and produce an abundance of water. The water quality is also a concern when planning an open-loop system. The amount of minerals in the water, the pH of the water, and the amount of biological growth all play a part in determining how suitable the water is for use in an open-loop system. Table 65-4 shows the acceptable levels of contaminants for open-loop use.

Open loops can be restricted by local government regulations. Regulations in some states do not allow water to be deposited back in the groundwater. In these states, open loops must be disposed of on top of the ground. Methods for handling the water include using holding ponds, draining to nearby running surface water, watering, and irrigation. Some states have regulations that require all discharged water to stay on the property. This makes running the water off on the surface impractical in most instances.

Open-Loop Well Systems

Water-source units are available with either copper or cupronickel water coils. Copper is fine for closed-loop systems, but open systems should use the more corrosion-resistant cupronickel. All piping should be either copper or schedule 80 PVC. Schedule 40 PVC is not acceptable due to the pressure and temperature extremes to which the piping will be exposed.

Shutoff valves should be included for ease of servicing. Boiler drains or other valves should be “teed” into the lines to allow acid flushing of the heat exchanger. Shutoff valves should be positioned to allow flow through the unit from the boiler drains without allowing flow into the piping system. P/T plugs should be used so that pressure drop across the unit and water temperature can be measured.

Ground-Loop Systems

All piping materials should be polyethylene for in-ground sections of the loop. All in-ground joints should be heat-fusion joined.

Galvanized or steel fittings should not be used at any time due to their tendency to corrode. Plastic to metal threaded fittings should also be avoided; due to the potential to leak in earth-coupled applications, a flanged fitting should be used instead. P/T plugs should be used going in and out of the unit so that the pressure drop across the unit can be measured to determine the water flow. Manual

shutoff valves should be located in the piping entering and leaving the unit. They should be able to isolate everything else from the loop.

65.5 SOLAR-ASSISTED SYSTEMS

Heat pumps and solar systems may be combined to improve the efficiency of both. Solar collectors lose efficiency as the temperature of the fluid in them increases. The fluid temperature in the solar collectors used for direct heat needs to be over 100°F, making the solar collectors inefficient. However, water-source heat pumps only need moderate-temperature water to operate. To a heat pump, 60°F entering water is hot. Solar systems can be used to raise the water temperature entering a water-source heat pump and increase the efficiency of both the solar collectors and the heat pump. The solar system transfers the heat to the water, and the heat pump transfers the heat from the water to the air.

65.6 START-UP PROCEDURES

A quality installation includes a careful system start-up procedure. It is important to follow a systematic start-up procedure to insure that the heat pump is performing as the manufacturer intended. Start-up should include a visual inspection, a prestart check, and system operational checks.

Visual Inspection

Make a thorough visual inspection of all equipment before turning anything on! Check to see that all packing materials and shipping bolts have been removed. Make sure all fans turn freely. Check to see that all wires have mechanical strain relief, that all equipment is properly grounded, and that all electrical connections are tight and properly made.

Prestart Inspection

Turn the thermostat system switch to OFF and the fan switch to AUTOMATIC so that the unit does not try to start. Turn the disconnect switch ON and check the incoming voltage. Compare the incoming voltage to the minimum and maximum voltage ratings on the data plate. Do not turn the unit on if the voltage is above or below these limits. Some units require that power be applied to the equipment for a period of several hours before turning it on. This is to allow any crankcase heat to drive refrigerant out of the oil in the compressor. If the equipment requires a long power-up period before operating:

1. Turn the power to the unit off.
2. Disconnect and tape the control wire that feeds the thermostat. (This is usually a red wire on the R terminal.)
3. Turn the power back on.
4. Return to complete the job the following day.

Airflow Check

Leave the system switch off and turn the fan switch to ON. The indoor fan should start. Some units will have a delay of several minutes before anything will happen after being

Table 65-4 Water Quality Standards

WATER QUALITY PARAMETER	HEAT EXCHANGER MATERIAL	RECOMMENDED SAFE LIMITS		
Scaling Potential—Primary Measurement				
Above the given limits, scaling is likely to occur. Scaling indexes should be calculated using the limits below.				
pH/Calcium Hardness Method	All	pH < 7.5 and Ca Hardness <100 ppm		
Index Limits For Probable Scaling Situations (operation outside these limits is not recommended)				
Scaling indexes should be calculated at 150°F for direct use and HWG applications and at 90°F for indirect HX use. A monitoring plan should be implemented.				
Ryznar stability index	All	6.0–7.5 If >7.5, minimize steel pipe use.		
Langelier saturation index	All	–0.5 to +0.5 If < –0.5, minimize steel pipe use. Based upon 150 °F HWG and direct well, 85°F indirect well HX.		
Iron Fouling				
Iron Fe ²⁺ (ferrous)(bacterial iron potential)	All	<0.2 ppm (ferrous) If Fe ²⁺ (ferrous) > 0.2 ppm with pH 6–8, O2 <5 ppm check for iron bacteria.		
Iron fouling	All	<0.5 ppm of oxygen Above this level deposition will occur.		
Corrosion Prevention				
pH	All	6–8.5 Minimize steel pipe below 7 and no open tanks with pH <8.		
Hydrogen sulfide (H ₂ S)	All	<0.5 ppm: At H ₂ S > 0.2 ppm, avoid use of copper and copper nickel piping or HXs. Rotten egg smell appears at 0.5 ppm level. Copper alloy (bronze or brass) cast components are OK to <0.5 ppm.		
Ammonia ion as hydroxide, chloride, nitrate, and sulfate compounds	All	<0.5 ppm		
Maximum chloride levels	Copper Cupronickel 304 SS 316 SS Titanium	Maximum allowable Chloride at maximum water temperature.		
		50°F (10°C)	75°F (24°C)	100°F (38°C)
		<20 ppm	NR	NR
		<150 ppm	NR	NR
		<400 ppm	<250 ppm	<150 ppm
		<1,000 ppm	<550 ppm	<375 ppm
		>1,000 ppm	>550 ppm	>375 ppm
Erosion and Clogging				
Particulate size and erosion	All	<10 ppm (<1 ppm “sandfree” for reinjection) of particles and a maximum velocity of 6 fps. Filtered for maximum 800 micron size. Any particulate that is not removed can potentially clog components.		

powered up. This delay only happens when power is first applied to the unit. Some units do have a slight delay after every call for fan operation. This delay is usually no longer than 30 seconds. After the fan starts, check the system airflow and compare it to the manufacturer's specifications. Any duct or airflow problems should be corrected before continuing. Note that the airflow in fan-only operation may not be the same as in cooling or heat.

TECH TIP

Units with ECM blowers usually circulate less air in fan-only operation than they do in cooling or heating. Make sure to compare the airflow to the fan-only specifications when checking airflow in the fan-only mode.

Air-Source Operational Check

Move the fan switch to the AUTO position. If the outdoor temperature is above 60°F, set the thermostat to call for cooling; otherwise, set it to call for heat. Check the voltage to the unit after the compressor has started and compare it to the voltage with the unit set to OFF. The operating voltage should be within 2 percent of the original voltage and should still be within the system parameters. Check the amp draw of the compressor and fans after the unit has operated for several minutes and the pressures have stabilized.

Compare the compressor reading to the rated load amps (RLA) on the data plate. Compare the blower readings to the full load amps (FLA) listed for each motor. The readings will usually not be exactly the same as the listing on the data plate, but they should be reasonably close. The actual current draw is affected by the load on the compressor and fan motors, which changes as the operating conditions change.

Check the system operating pressures and charge using whatever method is recommended by the manufacturer. Do not be too quick to adjust the charge. Look for other causes first if the pressures are incorrect! This is especially true with packaged units.

Filling the Water Loop

Newly installed loops normally have some debris in them, such as pipe shavings and dirt. The ground loop should be flushed with water to remove any debris before operating the system. Leaving the pipe shavings and dirt in the loop can damage the pumps and restrict the water flow. Flushing is done before the loop is connected to the system. After flushing, the loop is connected to the system.

The ground loop and heat pump must also be purged of any trapped air. Trapped air can block water flow, corrode metallic components, and cause pump failure. A purge unit is temporarily connected to the system to purge the system and to add antifreeze if necessary. If antifreeze is used, it is added to the water in the purge unit before purging starts. Only low-toxicity antifreeze solutions should be considered. In the event of a loop leak, the system could release toxic chemicals into the ground water if toxic antifreeze is used.

A water flow of 2 ft/sec is required to completely remove any trapped air. After purging the loop, pressurize it to at least 40 psig.

Water-Source Operational Check

The water flow on water-source systems needs to be checked immediately after calling for the unit to operate. The water flow rate can be checked by checking the pressure drop through the unit and comparing it to the manufacturer's specifications (Table 65-5).

Adjust the balancing valve to achieve a water flow within the manufacturer's specifications. The water temperature should be checked to be certain it falls within the allowable operating range (Table 65-6).

All other checks on a water-source system are useless if the water flow and temperature are not right! Once the water flow is correct, you can proceed to check the other system operating characteristics. The installation instructions for water-source heat pumps usually provide very detailed operational characteristics that can be used to check the system operation (Table 65-7).

Table 65-5 Example of Water-Source Heat Pump Pressure Drop and Flow Rate

Pressure Drop as Compared to Flow Rate and Entering Water Temperature*

**Entering Water temperature for a Flow Rate of 2.25 Gallons per Minute per Ton of Capacity.*

UNIT 65—SUMMARY

Installing a heat pump is not easy. There are many decisions to be made and many specific details to follow. The complexity is increased by the many types of heat pump systems available. There is simply not one way to install a heat pump, but many depending upon the specific application and system. One thing remains constant: reading and following all the manufacturer's installation instructions is the key to installing any type of heat pump system.

WORK ORDERS

Service Ticket 6501

Customer Complaint: High Heating Bills

Equipment Type: Split-System Heat Pump, Air Handler in Basement

A technician is called to look at a system that was installed 3 months ago. The customer complains that it keeps the house about 2° colder than the thermostat setpoint and costs almost as much to operate as the old electric furnace. The technician notes that even though the indoor unit is operating in the heating mode, the outdoor unit is not operating. The high-pressure switch is tripped. The unit starts after resetting the high-pressure switch but only stays on for about 10 minutes before it trips the pressure switch again. Reasoning that poor airflow can cause high pressures in heating, the technician measures the airflow and finds that it is much lower than the manufacturer's specification. In the installation manual, a drawing shows a minimum distance of 24 in before any takeoffs are to come off the plenum, but the installation has many takeoffs within the first foot. The technician asks the installation crew to return and install the duct according to the instructions.

Service Ticket 6502

Customer Complaint: No Heating

Equipment Type: Air-Source Packaged Heat Pump

A technician is called to check a heat pump that was installed 6 months ago. The customer complains that the unit operated fine all summer, but when she turned the thermostat to heat this fall, nothing happened. The technician notes that when the fan switch is switched to ON, the blower does not come on. The unit has 230 V at the contactor between L1 and L2, but there is no hum and the transformer is cold. The voltage between R and B, the common terminal, is 0. The transformer secondary winding resistance reading indicates an open circuit. The technician carefully inspects all the control wiring and finds that the blue wire in the thermostat bundle is connected to B both at the unit and at the thermostat.

However, the common terminal on the thermostat that was installed is terminal C. The B terminal is energized in heating. The technician moves the blue wire to the C terminal on the thermostat and replaces the transformer.

Service Ticket 6503

Customer Complaint: Warm Air in Cooling

Equipment Type: Water-Source Heat Pump Connected to Ground Loop

A technician is called to check a geothermal system that was just installed. The customer complains that the air leaving the registers is not very cold. The technician observes that the blower is running, but the compressor is not running. Further inspection reveals that the high-pressure switch is tripped. The water pump is drawing amps and is very hot, but there is very little pressure drop across the unit, indicating little or no water flow. When one of the purge valves is opened, air and water sputter out. The technician concludes that the loop still has air in it and needs to be purged and refilled.

Service Ticket 6504

Customer Complaint: Smoke Coming out of Heat Pump

Equipment Type: Split-System Air-Source Heat Pump

The customer has called in a panic. He looked out the window and saw billows of smoke coming out of the unit. A few minutes later the unit outside made a loud whooshing sound and got noticeably louder. The customer shut off the unit and called the shop immediately for help. The technician explains that it sounds like the customer just happened to see the unit at the end of the defrost cycle, which causes steam in cold weather. The whooshing noise was the system returning to heating mode. The technician completes a thorough system check to assure the customer that the system is operating correctly.

Service Ticket 6505

Customer Complaint: Cold Air in Heating Cycle

Equipment Type: Water-Source Heat Pump Connected to a Well

A technician is called out to check an open-loop ground-source system that has just been installed. The customer complains that the air in the heating cycle is cold. The technician notices that the isolation valves on the water lines to the unit are closed and the compressor is not running. The high-pressure switch has tripped because of the lack of water flow. The compressor comes back on after opening the water valves and resetting the high-pressure switch.

UNIT 65—REVIEW QUESTIONS

1. List the different configurations of air-source packaged heat pumps.
2. Give a common application for horizontal water-source heat pumps.
3. Explain the difference between an open loop and a closed loop.
4. List the types of loops geothermal heat pumps can use.
5. What are the main considerations when sizing an air-source heat pump?
6. How does oversizing a heat pump affect its efficiency?
7. What are some of the factors that should be considered when choosing a location for outdoor equipment?
8. Explain the following data plate ratings:
 - RLA
 - FLA
 - Minimum voltage
 - Maximum voltage
 - Minimum circuit ampacity
 - Maximum overcurrent protection
9. Plot the balance point for the following system.
 - Heating capacity at 47°F = 30,000 BTU/hr
 - Heating capacity at 17°F = 18,000 BTU/hr
 - House design heat loss at 20°F = 38,000 BTU/hr
10. How does the staging and sequence of operation for a dual-fuel heat pump system differ from a traditional heat pump with electric strip heat?
11. How should fiberboard duct be connected to a heat pump?
12. When are condensate pumps necessary?
13. How is the tubing used in ground-source systems joined?
14. Describe how a solar-assisted heat pump works.
15. List the steps required to fill a ground-source water loop for the first time.
16. Use Table 65-5 to determine the water flow through a model 038 water-source heat pump with a pressure drop across the unit of 2.3 psi if the water is at 70°F.
17. Use Table 65-6 to determine the maximum inlet water temperature for a GC model operating in heating.
18. How is the water flow through a water-source heat pump measured?
19. What steps must be taken when installing split-system units before opening the unit installation valves?
20. What items should be checked when converting an indoor air handler from upflow configuration to horizontal configuration?
21. How does the Carrier Infinity control system differ from traditional low-voltage control systems?
22. What type of antifreeze solutions may be used in ground loops?
23. Explain the difference between the two uses of the B terminal in heat pump controls.
24. What type of heat exchanger coil is best suited to open-loop well systems?

UNIT 66

Troubleshooting Heat Pump Systems

OBJECTIVES

After completing this unit, you will be able to:

1. list the common heat pump operating problems.
2. diagnose the symptoms and the corrective actions for heat pump problems.
3. describe the different types of heat pump defrost systems.
4. list the common problems associated with heat pump check valves.
5. discuss how to troubleshoot a heat pump reversing valve.
6. discuss how to troubleshoot heat pump defrost problems.
7. describe the airflow problems associated with heat pump operation.

66.1 INTRODUCTION

The heat pump is unique in design compared to other air-conditioning apparatus in that it operates year-round, both in summer and winter, cooling in one season and heating in the other. Because of this, the total operating time for a heat pump will be far greater, which invariably means more service. Even so, a properly maintained heat pump will last for many years.

Since heat pumps are a form of air conditioning, the technician's basic understanding of the fundamentals of air conditioning applies. Even with a water-source heat pump, air is still the principal medium used for transferring heat to the space to be conditioned. The correct quantity must be delivered at the correct temperature over the variations of winter and summer to provide comfortable conditions.

66.2 TROUBLESHOOTING GUIDELINES

In troubleshooting heat pumps, the technician must become thoroughly familiar with the controls and operating sequence of the particular design being serviced. Each design has its own selection of components and method of operation. To assist in finding a problem, many manufacturers describe helpful procedures in their installation and service bulletins.

It is important in troubleshooting heat pumps to find out as much as possible about the problem before starting a test procedure. Probably the most important question to ask first is, "Does the unit run or not run?" If the unit does not run, the first step is to check the power supply. Many heat pump failures are caused by thermostat malfunctions, a tripped circuit breaker, or a blown fuse. If the unit does run, find out what components run and what components do not run. If all the components operate, then investigate whether the problem occurs during the heating mode or the cooling mode.

Basically, the service problems with heat pumps fall into three main categories: air circulation problems,

refrigeration problems, and defrost problems, each of which is discussed in the following sections.

SERVICE TIP

Manufacturers have produced troubleshooting charts for their equipment. These charts are extremely beneficial in resolving problems, but they do not work as well when a system is mismatched. A mismatched system is one that has one manufacturer's outdoor unit and another manufacturer's indoor unit. In these cases, you will need to follow the troubleshooting skills that you will develop from the following unit material.

66.3 AIR SYSTEM PROBLEMS

The first check is the temperature drop through the evaporator. Assuming that the system airflow is correct, if the temperature drop is higher than specified by the manufacturer, the amount of air through the coil has decreased. Using the same refrigeration capacity on less air produces colder air. When in the cooling cycle, the inside coil must be able to remove the correct amount of sensible and latent heat from the air to produce the desired room conditions. Manufacturers publish the expected temperature drop through the coil (Table 66-1). The higher the indoor wet-bulb (wb) temperature, the lower the expected temperature drop. At 72°F, most systems have a temperature drop of only 10°F. This is because more of the unit's capacity is being used to remove water, so less is available to reduce the air temperature. At lower wet-bulb temperatures, the system is removing very little water and most of the capacity is going toward reducing the air temperature. At a 62°F wb, a temperature drop of 20°F is common. At AHRI design conditions of 67°F wb, systems typically have a temperature drop of approximately 15°F.

Table 66-1 Temperature Drop for Different Operation Conditions

Temperature Drop in Cooling					
Airflow	Wet Bulb	Indoor Dry Bulb			
		70°F	75°F	80°F	85°F
956 CFM	59°F	17°F	20°F	22°F	23°F
	63°F	15°F	18°F	21°F	23°F
	67°F	11°F	15°F	19°F	22°F
	71°F	NR	10°F	15°F	19°F
850 CFM	59°F	18°F	21°F	23°F	25°F
	63°F	16°F	19°F	22°F	24°F
	67°F	12°F	16°F	19°F	23°F
	71°F	NR	11°F	15°F	20°F
744 CFM	59°F	18°F	21°F	24°F	25°F
	63°F	16°F	19°F	23°F	25°F
	67°F	12°F	16°F	20°F	23°F
	71°F	NR	11°F	16°F	20°F

If the unit is in the heating cycle, the inside coil now acts as the condenser. The air will increase in temperature as it goes through the coil. The temperature rise across the coil decreases as the outdoor temperature drops. Table 66-2 shows common temperature rise information for different outdoor ambient temperatures based on nominal airflow through the coil of 400 CFM per ton and an indoor temperature of 70°F. A decrease in airflow will cause an increase in the temperature rise of the air across the inside coil. If the airflow reduction is severe enough, the unit will cut out on high head pressure. A repetitive cutting out of the compressor should be investigated and corrected before damage to the compressor results.

The heat pump operates on a year-round basis, and the amount of air through the inside coil is more critical than in a heating or air-conditioning system. Throwaway air filters

Table 66-2 Temperature Rise in Heating

(Airflow = 400 CFM per ton, 70°F return air)			
Outdoor Ambient	Temperature Rise	Outdoor Ambient	Temperature Rise
-10°F	7°F	25°F	18°F
-5°F	9°F	30°F	20°F
0°F	11°F	35°F	23°F
5°F	12°F	40°F	25°F
10°F	14°F	45°F	27°F
15°F	15°F	50°F	29°F
17°F	16°F	55°F	31°F
20°F	17°F	60°F	33°F

**Figure 66-1** Disposable panel filters should be checked monthly.

should be checked every 30 days (Figure 66-1). For high-efficiency air cleaning, it is advisable to use electronic air cleaners with heat pumps because these filters have a low static resistance even when dirty.

SERVICE TIP

Many customers interested in better filtration and cleaner air buy 1-in high-efficiency filters at home improvement stores. Unfortunately, many of these have a very high static pressure drop even when the filter is new. If a customer wants a better filter, suggest installing a 4- or 5-in media filter. These offer the filtration they want without choking off the airflow.

66.4 BLOWER MOTOR PROBLEMS

Inspection of the blower and drive should be done at least once a year. Most heat pump blower motors today use permanently lubricated bearings that do not require lubrication. You should lubricate the blower motor only if it has oiler holes. The motor should be lubricated with no more than ten drops of No. 20 electric motor oil. Excessive lubrication can lead to dirt sticking to the oiling ports, which can contaminate the bearings. Always use detergent-free oil. Automobile oil is discouraged because it has detergent (soap), which coats the outer surface of the sintered bronze bearing and prevents oil passage through the bearing.

SERVICE TIP

Never lubricate blower motors anywhere except at the oiler holes. Trying to lubricate motor parts by just squirting oil on them will likely do more harm than good. If a motor does not have oiler ports, do not try to oil it.

Figure 66-2 Check the blower motor amp draw and compare it to the motor full-load amp (FLA) rating.

Check the amp draw of the blower motor while it is operating and compare it to the full-load amp rating (Figure 66-2). An amp draw significantly higher than full-load amps could indicate a problem. Keep in mind that the amp draw will vary based on the load on the motor. If the motor is suspected to be faulty, a resistance check of the motor windings should be performed. The motor windings should show a measureable resistance: not infinite (OL) and not 0 (Figure 66-3). An infinite reading indicates an open winding; a reading of less than 1 ohm indicates a shorted winding. However, if the motor is hot, an infinite reading may just indicate that the internal thermal overload is open. Wait for a hot motor to cool before condemning it. If the windings are either open or shorted, the motor will need to be replaced. If the motor needs replacing, it is generally recommended to replace the capacitor as well.

Figure 66-3 The motor windings should have a measurable resistance.

GREEN TIP

Brushless DC motors are available to replace standard PSC motors used in many heat pump blowers. The brushless DC motors are considerably more energy efficient and will save on the system operating cost and energy use.

66.5 MEASURING SYSTEM AIRFLOW

The two most common methods of measuring the airflow is to either read the static pressure across the unit and compare it to the unit specifications or to operate the unit in emergency heat and measure the temperature rise.

Measuring External Static Pressure

Manufacturers specify the unit airflow at different external static pressures. External static pressures are created by the resistance of the ductwork and other components mounted outside of the unit. This can be measured using a magnehelic gauge, an inclined manometer, or a digital manometer. To measure the external static pressure, drill a 1/4-in hole in both the return and supply plenum. Place a static pressure probe in each hole. Connect the return probe to the low side of the manometer or magnehelic and the supply probe to the high side of the manometer or magnehelic (Figure 66-4).

SERVICE TIP

External static pressure readings are taken using the filter that ships with the unit. If the low-pressure drop filter that comes with the unit has been replaced with a filter with a higher pressure drop, readings taken at the return plenum will be inaccurate. In this case, drill a hole in the return side of the blower cabinet. Be careful not to drill into components located in the lower half of the cabinet. Take off the unit covers to make sure you know where you are drilling.

Figure 66-4 Measuring the total external static pressure.

CFM Delivered Against Total External Static Pressure					
Speed	0.1 in wc	0.2 in wc	0.3 in wc	0.4 in wc	0.5 in wc
High	1,155	1,090	1,025	950	895
Medium	940	890	860	815	755
Low	695	665	650	610	550

Figure 66-5 Blower performance table showing airflow against external static pressure.

Operate the blower and read the external static pressure. Compare your reading to the manufacturers chart. For example, in Figure 66-5, a blower operating on low speed with an external static pressure reading of 0.4 in external static would indicate an airflow of 610 CFM. You should have approximately 400 CFM per ton. An airflow of 610 CFM would not be enough for a 2-ton unit. On the other hand, the same reading with the blower operating on medium speed would indicate an airflow of 815 CFM, which would be fine for a 2-ton unit. To make much sense of external static pressure readings, you must have the manufacturer's data for that particular model unit.

Measuring Temperature Rise

Many manufacturers recommend using the temperature-rise method with heat pumps because it only requires measuring voltage, amperage, and air temperature. Operate the unit in emergency heat mode and measure the voltage and amperage of the electric strip heaters (Figure 66-6). Measure the return-air and supply-air temperatures near the unit. Calculate the BTUH using this formula:

$$\text{CFM} = (\text{volts} \times \text{amps} \times 3.41) / (1.1 \times (\text{supply-air temperature} - \text{return-air temperature}))$$

Figure 66-6 Measuring the voltage and amp draw of the strip heaters.

For example, strip heaters pulling 40 A on 230 V with a return-air temperature of 70°F and a supply-air temperature of 100°F would be

$$\text{CFM} = (230 \text{ V} \times 40 \text{ A} \times 3.41 \text{ BTUH/watt}) / (1.1 \times (100^\circ\text{F} - 70^\circ\text{F}))$$

$$\text{CFM} = (9,200 \text{ watts} \times 3.41 \text{ BTUH/watt}) / (1.1 \times 30^\circ\text{F})$$

$$\text{CFM} = 31,372 / 33 = 950 \text{ CFM}$$

SERVICE TIP

When taking the supply-air temperature, make sure that there is not a direct line of sight between the thermometer and the heat strips. If the thermometer can “see” the strips, it will read slightly higher temperature.

Duct System Problems

High external static pressures can be caused by poor ductwork. Unfortunately, poor duct systems are all too common. Unusual restrictions in the duct system, such as closing off unused rooms and placing furniture or carpeting over supply and/or return grilles, will cause coil frosting in the cooling cycle and unit cutoff in the heating cycle. This practice has a greater effect on the heating cycle than on the cooling cycle.

Failure of the duct system also has a greater effect in the heating cycle than in the cooling cycle. With 70°F in the occupied area, the supply-air temperature will only be in the range of 100°F to 105°F when the outdoor temperature is 60°F to 65°F and down to the 80°F range when it is –10°F outside. Any leakage in the duct system will therefore seriously reduce the capacity of the unit to handle the heating load. When this happens, more auxiliary heat will be required and as a result, the operating cost will be higher than normal.

SERVICE TIP

Heat pumps have higher airflows for the same heating capacity than other heating systems, and their air supply temperature is lower than other heating systems. This often results in customers complaining that heat pumps are cold and drafty. To prevent this problem, the supply registers should have deep curved louvers so that the air is directed across the ceiling and not down into the room. By directing the air away from room occupants, they are not as likely to feel a cold draft. Most register manufacturers have a specific designed series of registers for heat pumps.

SERVICE TIP

The first step in checking a suspected refrigeration system problem is to check the airflow. Many systems with airflow problems are misdiagnosed as having refrigeration problems. If the airflow is not correct, you are wasting your time looking for a refrigeration problem.

66.6 REFRIGERATION SYSTEM PROBLEMS

When the temperature change across the inside coil is less than it should be on the cooling or heating cycle, the refrigeration system should be suspected. As in an air-conditioning system, this is generally classified into two categories:

- Refrigerant quantity
- Refrigerant flow rate

If the system has the proper amount of refrigerant and it is flowing at the desired rate, the system will work properly and deliver the rated capacity. Any problem in either category will affect the temperatures and pressures developed in the unit when the correct amount of air is supplied over the inside coil.

66.7 REFRIGERANT QUANTITY PROBLEMS

If the system is low on refrigerant, the measured operating pressures will be below normal, the superheat will be high, and the subcooling will be low. In addition, the compressor will run for longer periods even at times when the cooling demand is not extremely high. The compressor may be running hotter than normal due to a lack of refrigerant flow, which helps to cool it. On a newly installed system, a low refrigerant charge may be the result of improper installation. Although many new units come precharged, additional refrigerant may be required depending on the length and size of refrigerant piping. If this was not taken into account on installation, the system will require additional refrigerant for proper operation.

SERVICE TIP

Some systems have a hot gas sensor control that is wired in series with the compressor contactor and shuts down the unit if excessively high discharge temperatures are reached. If the hot gas sensor switch opens, this could be the result of a low level of refrigerant in the system. Due to the shortage of refrigerant, the compressor motor normally cooled by the suction vapor will heat up. The gas passing through the compressor will therefore be hotter than normal, indicated by a high compressor discharge temperature.

Whenever adjusting the charge for any refrigeration system, the manufacturer's recommendations must be followed (Figure 66-7). Too much refrigerant will increase the system's operating pressures and temperatures, making the compressor work harder. This leads to an increase in the power required, and the compressor will run hotter than normal.

Figure 66-7 Subcooling charging chart.

SERVICE TIP

The high-pressure switch is wired in series with the compressor contactor and shuts down the unit if excessively high discharge pressures are reached. One possible cause of this switch opening is a refrigerant overcharge, which will lead to an increase in the compressor discharge pressure.

Too much refrigerant could also lead to an increased amount of liquid in the evaporator coil and possible floodback to the compressor. If a system is experiencing floodback, the suction line superheat will be low. Many systems have suction-line accumulators located after the evaporator that are sized to hold the full system charge. If the accumulator capacity is reached, the liquid refrigerant will flow from the accumulator into the compressor suction line, possibly causing damage. This is most likely to happen at the completion of the defrost cycle when the system is switching back into the heating mode.

Frost buildup on the indoor coil, as shown in Figure 66-8, is normally caused by either low airflow or too little refrigerant. On an existing unit, a low refrigerant level is generally an indication of a leak. If this is the case, then simply adding additional refrigerant is never recommended. Any remaining refrigerant must be recovered from the system, and the leak must be found and repaired. The system must then be evacuated thoroughly and recharged with the correct amount of refrigerant.

CAUTION

During the heating mode, the vapor line on a heat pump is at the higher discharge pressure of the system. Make sure not to automatically attach the low-pressure gauge to the vapor line. To do so can damage your low-pressure gauge. There is a low-pressure port that is between the reversing valve and the compressor.

Figure 66-8 Ice buildup on coil. (Courtesy of InspectAPedia.com)

66.8 COLD WEATHER REFRIGERANT CHECK

As the outdoor temperature drops, the capacity of an air source heat pump drops because the compressor must work against increased pressure difference due to the lower evaporator temperature and pressure. Less refrigerant is circulated because of the increased compression ratio and diminished compressor capacity. The refrigerant that is not being circulated must sit somewhere, usually in the accumulator. For this reason, a charge which is adequate to maintain correct pressures and temperatures at 25°F may not be adequate at 35°F. Just adding a little extra refrigerant is not a good idea either because there is no way to determine how much extra to add. This is why manufacturers say that a heating performance check chart should not be used to charge the system, only to check its operation. If the system is undercharged, the recommendation from many manufacturers is to recover the refrigerant in the unit, evacuate the system, and weigh in a total system charge according to the manufacturer's instructions.

Methods used to check system performance in the heating cycle include

- System pressure charts that correspond to indoor and outdoor temperatures
- Indoor air temperature rise that corresponds to outdoor temperature

Figure 66-9 Schematic diagram of a conventional air-conditioning/refrigeration system.

- Discharge line superheat (usually 50°F to 60°F)
- Discharge line approach (usually 100°F to 110°F above ambient)

66.9 REFRIGERANT FLOW PROBLEMS

To troubleshoot refrigerant flow problems, a detailed understanding of the system configuration is essential. Figure 66-9 shows a conventional air-conditioning system. This system shows the refrigerant flow from the discharge of the compressor to the outside coil, in this case the condenser. The refrigerant condenses and flows from the outside coil through the liquid line, through the filter drier and expansion device, and into the inside coil, in this case the evaporator. The refrigerant expands, picking up heat in the evaporator, and then flows as a vapor to the compressor.

In Figure 66-10, the same action takes place, except that additional devices to accommodate the reverse flow have been added. A reversing valve is located between the suction and discharge lines to enable the system to reverse the flow of refrigerant. In the cooling mode, the position of the reversing valve directs the flow the same way as in the conventional air-conditioning system. However, unlike the conventional system, an expansion device has been added to the outside coil, allowing it to operate as an evaporator during the heating cycle. In addition, two check valves are added to allow for bypassed flow around each expansion device dependent on the operating mode.

Figure 66-11 shows the flow of refrigerant through the system in the heating mode. The reversing valve directs the hot refrigerant vapor to the inside coil, in this case the condenser. Heat is transferred to the air supplying the conditioned space. The hot refrigerant vapor cools, condenses, and flows out of the bottom of the condenser. With the flow reversed, check valve #2 opens and allows the liquid refrigerant to flow around the cooling-cycle expansion device to eliminate any pressure loss. Since check valve #1 will not allow for flow in this direction, the refrigerant passes

Figure 66-10 Schematic diagram of a heat pump system used for cooling, showing the position of the reversing valve.

Figure 66-11 Schematic diagram of a heat pump system used for heating, showing the position of the reversing valve.

through the heating-cycle expansion device. Entering the outdoor coil, in this case the evaporator, the liquid refrigerant, at a lower pressure and boiling point, vaporizes as it picks up heat from the outside air. The vaporized refrigerant flows through the reversing valve and the accumulator to the compressor.

TECH TIP

The only reversing of the refrigerant flow is from the reversing valve through the coils, pressure-reducing devices, and check valves. The refrigerant vapor always flows from the reversing valve, accumulator, and compressor back to the reversing valve. Although the flow of refrigerant through the system reverses, the flow through the compressor never changes.

66.10 CHECK VALVES

Check valves allow for flow in one direction only. An operational problem encountered with these valves is sticking in either the open or closed position. With this type of malfunction, the flow in only one direction would be affected. The system will therefore work correctly in one cycle but not the other, dependent on the valve's location in the system. This type of problem is somewhat easy to identify, because if the valve is doing what it is supposed to, the system will operate properly. If not, the problem will show up.

Common problems include the following:

- *The check valve installed to bypass the cooling-cycle expansion device on the indoor coil sticks in the open position.* The system will operate properly in the heating mode, as the check valve is normally open in this cycle. In the cooling mode, however, the cooling-cycle expansion device is bypassed, allowing for uncontrolled refrigerant flow into the indoor coil. The refrigerant will flood through the coil, the suction pressure will be high, the discharge pressure will be low, and the suction-line accumulator will fill with liquid refrigerant. In this case, the possibility of liquid flooding back to the compressor exists.
- *The check valve installed to bypass the cooling-cycle expansion device on the indoor coil sticks in the closed position.* The system will operate properly in the cooling mode, as the check valve is normally closed in this cycle. In the heating mode, however, the suction pressure will be much lower than normal. This is because the normal flow, rather than being bypassed, is restricted by the expansion device. This restriction to flow allows for a reduced amount of refrigerant to enter the outdoor coil and return in the suction line to the compressor. At the same time, the discharge pressure will be low due to the reduced amount of vapor available for the compressor to pump. The symptoms of this condition are similar to those of an undercharge, but the difference is that the system will operate normally in the cooling mode. This can be easily checked by switching to the opposite cycle.
- *The check valve installed to bypass the heating-cycle expansion device on the outdoor coil sticks in the open position.* The system will operate properly in the cooling mode, as the check valve is normally open in this cycle. In the heating mode, however, the heating-cycle expansion device is bypassed, allowing for uncontrolled refrigerant flow into the outdoor coil.

The result is similar to what happens when the check valve installed to bypass the cooling-cycle expansion device sticks open.

- *The check valve installed to bypass the heating-cycle expansion device on the outdoor coil sticks in the closed position.* The system will operate properly in the heating mode, as the check valve is normally closed in this cycle. In the cooling mode, however, the suction pressure will be much lower than normal. This is because the normal flow, rather than being bypassed, is restricted by the expansion device. The result is similar to what happens when the check valve installed to bypass the cooling-cycle expansion device sticks closed.

Usually, a check valve can be released from the stuck-open position by means of a magnet placed against the outlet end of the valve. Moving the magnet toward the center will force the ball or flapper to move to the seat. If in the stuck-closed position, place the magnet at the middle of the valve and move it to the outlet end. If this does not work, replace the valve. To reduce the possibility of future problems, use a ball-type check.

66.11 REVERSING VALVES

Figure 66-12 shows the exterior view of a reversing valve. The single tube connection is always connected to the compressor discharge. The bottom middle connection is always connected to the compressor suction connection. When an accumulator is in the circuit, this connection is to the accumulator inlet. The accumulator outlet is then connected to the compressor suction. This puts the accumulator upstream from the compressor and provides protection in either the heating or cooling mode.

The right and left connections are to the vapor line connection of the indoor and outdoor coils. Which connection goes where depends on whether the operating solenoid coil is energized for heating or energized for cooling. If the solenoid coil is energized in cooling, a bad solenoid coil will cause the unit to operate in the heating mode anytime the compressor runs. If the solenoid coil is energized in heating,

Figure 66-12 Reversing valve.

a bad solenoid coil will cause the unit to operate in the cooling mode anytime the compressor runs.

Before checking the position of the valve operation, the electrical control system should be checked to determine the operating requirements of the valve. Valves that operate in cooling are usually energized by the O terminal on the thermostat, while valves that are energized in heating are usually energized by the B terminal on the thermostat.

CAUTION

Do not energize the reversing-valve solenoid coil when it is not installed on the reversing valve. The solenoid coil can quickly overheat and burn out.

Problems in reversing valves are either electrical or mechanical. Electrical problems are confined to the solenoid coil on the pilot valve. When the solenoid coil is energized and nothing happens, test the coil as follows:

- Feel the solenoid coil. If it feels hot, the coil is energized.
- Make sure that voltage is applied to the solenoid coil. Some units have the coil in the 240 V portion of the system, while others use it in the 24 V portion. Check the wiring diagram for coil voltage before applying the leads of the voltmeter. Also, start the test with the voltmeter set to the higher range. This helps reduce meter damage.
- With voltage applied to the solenoid coil, remove the coil holding nut and attempt to pull the coil off the pilot valve plunger casing. If you feel resistance to removing the coil, the coil is active (Figure 66-13). If no pull is felt, shut off the power, remove the coil heads, and check for continuity with the ohmmeter (Figure 66-14). If open, replace the coil. If a circuit exists, check the leads and the connections for continuity.

Figure 66-13 Briefly pull the solenoid coil part way off while energized to check the pilot valve operation.

Figure 66-14 Checking the resistance of the reversing-valve solenoid coil.

- If the solenoid coil is active, when removing the coil, a click should be heard when the pilot plunger returns to the normally closed position. If no clicks are heard, the pilot valve is stuck. The only repair is to replace the reversing valve.

When the pilot valve checks out satisfactorily and the main valve does not shift, make sure that suction and discharge show more than a 100 psig difference. If the valve is in the cooling position, block off the air to the condenser with plastic on the inlet face of the coil. Allow the unit to operate until the condensing saturation temperature rises to 130°F. With the unit operating, cycle the valve on and off several times. This will usually free the main valve to operate again. If no results are achieved, change the valve.

SERVICE TIP

If the heat pump is operated for any period of time in the heating mode in warm weather, the compressor can become overloaded. If it is necessary to run the heat pump in the heating mode for testing purposes when the weather is warmer than 60°F, you should cover the coils to restrict the airflow. This will prevent the heat pump from picking up excessive amounts of heat and overloading the compressor while the system is being tested.

When changing a reversing valve, be sure to read the installation instructions supplied with the valve. The first step is always to recover the entire system charge. Replace the valve with one of a comparable size. Never use a valve with a smaller body or line ports. Always position the valve so that the main piston is in a horizontal position and the pilot valve is higher than the main valve. This is to keep oil from gathering in the pilot valve and affecting its operation.

The valve body must always be protected from heat when installing by wrapping the body with some type of thermoplastic material or wrapping with a water-saturated cloth. The maximum temperature the valve body will tolerate is 250°F.

SERVICE TIP

If it is necessary to replace the heat pump reversing valve, the new valve must be protected from overheating during brazing. The valve contains plastic gaskets and seals that are easily damaged from excessive heat. Wrapping a wet rag around the valve body will help prevent overheating. In addition, an oxyacetylene torch with a large enough flame to heat the fitting quickly should be used.

66.12 DEFROST SYSTEM PROBLEMS

Defrosting is required when the unit is running in the heating mode. In this case, the outdoor coil is the evaporator and is absorbing heat from the outside air. Depending on the outside air temperature and humidity conditions, the cold outdoor coil will develop frost. When the defrost cycle is initiated, the system temporarily reverses to send hot gas to the outdoor coil, which melts any frost that has formed. However, in this defrost mode, cold rather than hot air is delivered to the conditioned space. To reduce this effect, the fan for the outdoor coil shuts off and the auxiliary heat comes on for the duration of the defrost cycle.

If the defrost cycle is not initiated frequently enough, the outdoor coil will develop more and more frost until the frost turns to sheets of ice on the coil (Figure 66-15). If the defrost cycle is initiated too often, the efficiency of the system is decreased and energy is wasted, increasing the cost of operation. To diagnose problems in the defrost system, the type of defrost must first be determined. The four most predominant defrost systems are covered here. On those systems used by individual manufacturers, the manufacturer should be contacted for service information.

Figure 66-15 Heavy frost buildup starting to form into an ice sheet.

66.13 TEMPERATURE-DIFFERENTIAL DEFROST SYSTEM

This defrost system measures the temperature difference between the outdoor ambient temperature and the coil temperature. Although the coil temperature will drop as the outdoor temperature drops, the temperature difference between the outdoor air and the coil remains about the same under normal operation. However, when enough frost forms on the coil to restrict airflow across it, the coil temperature will drop even if the outdoor temperature remains the same, increasing the temperature differential between the outdoor air and the outdoor coil. Temperature differential defrost controls initiate a defrost cycle whenever the temperature differential between the outdoor temperature and the coil temperature increases beyond the normal operating differential.

The Unit Will Not Go into Defrost

This is the most common complaint on this type of system. The control is operated by the difference between the temperature of the air entering the outdoor coil (the evaporator) and the coil temperature itself. The predominant reason that the unit will not go into defrost is that the coil will not reach a low enough temperature to provide an increase in the control differential to activate the defrost cycle. The major reason for this is that the discharge pressure is too high, which forces the suction pressure and coil boiling point up. Only a 2°F rise in boiling point can result in the system needing complete coverage of the coil with frost and ice before the system initiates the defrost cycle.

The technician should never attempt to adjust the control, which is not possible in the field. Before replacing the control, the technician should determine the cause of the problem. If the discharge pressure is too high, this can very often be attributed to an airflow problem. The duct system may be inadequate, the indoor coil may be dirty or plugged, or the blower may not be operating properly. With a reduced airflow through the indoor coil, the discharge pressure will increase. The correct solution to this is to restore the correct flow of air over the indoor coil to design conditions. This will lower the head pressure and the suction pressure.

The Unit Goes into Defrost with Very Little Frost on the Bottom of the Outdoor Coil

The location of the outdoor coil temperature-sensing thermistor is critical. The thermistor should be located in the original location selected by the manufacturer. This can vary quite a bit from one manufacturer to another. If the coil temperature sensing thermistor has come off, try to determine where it was originally located.

The Unit Does Not Defrost the Entire Coil

This can result in an ice ring building up around the bottom of the coil. The ice buildup indicates that the coil temperature bulb is located too high on the coil. The coil has to reach a preset temperature to terminate the defrost cycle. Usually, this temperature is 50–60°F. Most demand boards have a

programmed maximum defrost time. They will terminate the defrost cycle even if the defrost is not complete. Failure to complete the defrost can be caused by not defrosting frequently enough, a slight refrigerant undercharge, the outdoor fan continuing to run in defrost, or incorrect coil thermistor sensor placement. A slight undercharge can cause more frequent icing. It also reduces the amount of heat available during defrost. If the fan continues to operate and blow cold air across the coil, there will not be enough heat to defrost it.

66.14 PRESSURE-TEMPERATURE DEFROST SYSTEM

In this system, the airflow pressure differential across the outdoor coil initiates the defrost cycle and the temperature of the liquid leaving the coil terminates it. When the frost buildup causes enough airflow resistance to close the differential pressure switch, the defrost cycle is initiated. The cycle is reversed and hot gas flows into the outdoor coil, which is now acting as a condenser. The defrost cycle will end as the outdoor coil begins heating up and the liquid leaving reaches 55°F.

The defrost thermostat also controls the possibility of a defrost cycle. A thermostat fastened to the coil is exposed to the expanding liquid refrigerant when the unit is operating in the heating cycle. If the evaporator coil is operating with an entering liquid of 26°F or higher, there is little chance that frost will form on the coil. If this temperature is below 26°F, the thermostat closes and completes the circuit through the defrost relay to the differential pressure switch.

The Unit Will Not Go into Defrost

Two possible causes can prevent the unit from going into defrost. The most probable cause is that the termination thermostat has come loose from the coil outlet pipe. The thermostat cannot reach 26°F or below to close and allow the defrost circuit to initiate. The other probable cause is plugged tubes to the differential pressure switch. Insects sometimes plug these pipes. Check to see that the tubes are located correctly, connected to the differential air switch, clear of insects and debris, and not cracked or broken.

The Unit Goes into Defrost with Very Little Frost on the Bottom of the Coil

Because the pressure drop of the air through the coil is the determining factor for initiating the defrost cycle, both the cleanliness of the coil and the frost buildup make up this pressure drop. Therefore, the more dirt buildup on the coil, the less frost has to form to reach the required pressure drop to initiate the defrost cycle. When the unit starts defrosting with little frost buildup, clean the coil.

The Unit Does Not Defrost the Entire Coil

This can result in an ice ring forming at the bottom of the coil. This is an indication that the defrost cycle is interrupted before the defrost cycle is completed. Many systems have an automatic defrost cycle termination anywhere from 5 to 12 minutes, which can be set dependent on the outside weather conditions and humidity. This ensures that no matter what

may affect any of the other controls, the defrost cycle will not continue indefinitely. If the defrost cycle is ending too quickly, then the automatic termination needs to be adjusted to extend the period of the defrost cycle.

Another reason for incomplete defrost can be from a combination of the indoor thermostat setting and the auxiliary heat. In the defrost cycle, auxiliary heat comes on to offset the effect of supplying cold air to the conditioned space. If the auxiliary heat is great enough to warm the occupied area, the room thermostat may open before the defrost cycle is completed and the unit will shut down. The incomplete defrost cycle will leave an ice buildup at the bottom of the coil until the unit restarts on the next heating demand. In most cases, the unit will usually restart in the defrost cycle and then continue until defrosting is completed.

The alternate thawing and freezing of the water held on the coil by the ice coating can lead to a collapse of the coil tubes and loss of refrigerant. To correct this problem, reduce the amount of auxiliary heat used in the defrost cycle to an amount not more than the sensible capacity of the unit on the cooling cycle.

66.15 TIME-TEMPERATURE DEFROST SYSTEM

This system uses a board with timing circuit in combination with a temperature-sensing device called a defrost thermostat (Figure 66-16). The timer counts down the defrost starting time whenever the unit is running in heat. When the defrost time is reached, the timer will always try to initiate the defrost cycle. However, if the defrost temperature is not low enough, generally below 26°F, the defrost will not begin. The timer will reset, and a new countdown starts until the next defrost begins. The time periods are adjustable by moving a jumper or switch on the board.

The Unit Will Not Go into Defrost

The most common cause of this problem is a loose defrost thermostat. A poor contact between the thermostat and the coil tube prevents the thermostat temperature from

dropping below 26°F. If poor contact is not the problem, then the thermostat should be checked to determine if it closes at a temperature below 26°F. Immersion in an ice and saltwater bath using an immersion thermometer will accomplish this.

The Unit Goes into Defrost with Very Little Frost on the Bottom of the Coil

The timer may be operating on too short a cycle time. Most defrost boards have several possible time settings between 30 and 90 minutes. Change the timer to a higher setting if the unit defrosts too frequently.

The Unit Does Not Defrost the Entire Coil

This can result in an ice ring forming at the bottom of the coil. This is an indication that the defrost cycle is interrupted before the defrost cycle is completed. As noted earlier in Section 66-13, one correction to this problem is to adjust the automatic termination to extend the period of the defrost cycle, and another is to reduce the amount of auxiliary heat used in the defrost cycle to an amount not more than the sensible capacity of the unit on the cooling cycle. Also, check to see that the outdoor fan shuts off during defrost. Finally, a slight undercharge can cause this problem.

SERVICE TIP

Time defrost systems can be set for various defrost intervals. These are typically 30-, 60-, and 90-minute intervals. The higher the relative humidity, the more frequently the system should defrost to reduce the chance of excessive frost buildup. However, the more frequent the defrost time, the less efficiently the system will operate. Therefore, the defrost cycle should be adjusted to go on and off no more than what is required to eliminate any frost buildup. It is recommended that you check with your local supplier for their recommendation on defrost time settings for your geographical area.

Figure 66-16 Standard time-temperature defrost control.

66.16 PRESSURE-TIME-TEMPERATURE DEFROST SYSTEM

This system uses a differential airflow pressure switch to measure the amount of frost on the outdoor coil. When the pressure drop through the coil reaches a preset amount, the switch closes the timer circuit. If the defrost thermostat is below 26°F, the timer will operate. This timer usually requires 5 minutes of pressure switch closure time to initiate the defrost cycle by energizing the defrost relay. When the termination thermostat reaches 55°F, the power to the defrost relay is interrupted and the unit changes over to the heating cycle.

The Unit Will Not Go into Defrost

The most common cause of this is a loose or poorly connected termination bulb of the defrost control. It is very important that the bulb be securely fastened with

heat-transfer compound on the joint, insulated, and sealed from moisture. Ice can build up at this location and loosen the bulb fastening. The second cause can be failure of the pressure switch due to dirt and/or insects in the pressure switch tube connections. There is always the possibility of failure of the timer control, but this is remote. Check the previous two items before replacing any parts.

The Unit Goes into Defrost with Very Little Frost on the Bottom of the Coil

The major cause of this action is a dirty outdoor coil. Its frost-free resistance is so high that it takes very little increase in pressure drop to start the defrost cycle. A thorough coil cleaning is in order.

The Unit Does Not Defrost the Entire Coil

This is an indication that the defrost cycle is interrupted before the cycle is completed. As noted earlier in Section 66-13, one way to correct this problem is to adjust the automatic termination to extend the period of the defrost cycle, and another is to reduce the amount of auxiliary heat used in the defrost cycle to an amount not more than the sensible capacity of the unit on the cooling cycle.

66.17 FORCING A DEFROST CYCLE

Most defrost boards have test jumpers to allow technicians to check the defrost board operation. The first step is to make sure the defrost thermostat is cold enough to allow a defrost. If the coil is not frosted, disconnect the outdoor fan and operate the unit in heating until the area where the defrost thermostat is located is frosted. Next, find the test pins and short them together (Figure 66-17). This speeds up time. Normally, minutes become seconds, so a 60-minute timing period becomes a 60-second timing period. The unit should go into defrost after a short delay. Typically, the unit will remain in defrost until the defrost thermostat senses that the coil is 50–70°F. If the system will not go into defrost, you need to try fooling the board into thinking the coil is cold. With time-temperature boards that use defrost thermostats, the defrost thermostat connections can be jumped out on the board. For boards that use thermistors, disconnecting the coil thermistor simulates a very cold temperature because most of the thermistors used with defrost

Figure 66-18 Defrost thermostat and defrost thermistor.

boards are negative-temperature coefficient. A high resistance means a low temperature. If the board still will not go into defrost, the board needs to be replaced. It is important to know which type you have. Shorting out the thermistor could damage the board. Defrost thermostats are larger and have larger-gauge wires. Thermistors are small with much smaller wires. Figure 66-18 shows a defrost thermostat on the top and a defrost thermistor on the bottom.

Figure 66-17 Shorting across the test pins speeds up the timing functions of the board.

UNIT 66—SUMMARY

Service problems with heat pumps fall into three main categories: air circulation problems, refrigeration problems, and defrost problems. Air circulation problems for heat pumps are similar to those encountered with general air-conditioning systems. However, one significant difference is that heat pumps have higher airflow per ton than other heating systems and their air supply temperature is lower than other heating systems.

Refrigeration problems are generally categorized as refrigerant quantity or refrigerant flow problems. Heat pumps have a number of different components compared to conventional refrigeration systems, such as reversing valves, check valves, and bidirectional expansion devices. It is important for the technician to understand why these components are required and how they are installed and operated.

The heat pump defrost system is essential to maintain proper operation during the heating mode. During this cycle, the outdoor coil is subject to icing dependent on the outside air temperature and humidity. The defrost cycle needs to be initiated early enough to eliminate the formation of ice but not so often as to reduce the unit's efficiency.

WORK ORDERS

Service Ticket 6601

Customer Complaint: Room Too Drafty

Equipment Type: Air-Source Packaged Heat Pump

The technician answers a service call for a customer complaining that the home is too drafty and that cold air is blowing from the registers all of the time. The first thing that the technician checks is the thermostat setting. There are three settings available: ON, OFF, and AUTO. The blower is set to the ON position, which allows it to run continuously whether the heat pump is operating or not.

The technician asks the customer about this, and the customer explains that the thermostat was originally set for the AUTO position, but because it always seemed so drafty she changed it to the ON position hoping to blow more air into the room.

The technician tells her that this would not increase the heat and that the unit is designed to work best with the blower in the AUTO position. If it is not supplying enough heat, then there could be other reasons. The technician reviews the original specifications for the unit, and it seems to be sized properly for the heating load. The air supply registers are also properly located so as not to induce unnecessary drafts.

However, it has been unusually cold in the area during the past month, and this type of a system would require additional auxiliary heat as the temperature has been dropping below freezing. The technician finds that one of the electrical strips for the auxiliary heat has failed and so that is replaced. With the blower on AUTO and the electric auxiliary heat operational, the house is no longer drafty for the customer.

Service Ticket 6602

Customer Complaint: High Energy Cost

Equipment Type: Split-System Air-Source Heat Pump, Air Handler in Basement

The customer tells the technician that his electricity costs have been fairly stable since installing the heat pump 5 years ago. However, most recently, the electricity cost has increased significantly and he is wondering if this is because the system is getting older and worn out.

The technician tells him that that should not be the case as long as regular maintenance is conducted, which the records indicate. He does mention, however, that some landscaping was done just a month or so back in the vicinity of the outdoor coil. Inspecting the manual for the unit, the technician finds it has a pressure-time-temperature defrost system. This is a fairly elaborate system, but it is also generally very efficient in regulating the timing for the defrost cycle.

Removing the outside protective grille from the outdoor coil, the technician finds it to be extremely dirty.

It is covered with dust, leaves, and grass. Evidently, the landscaping work had stirred up this debris, which was drawn into the outdoor coil. The pressure drop of the air through the coil is the determining factor for initiating the defrost cycle for this type of unit. Due to the dirt buildup on the coil, less frost has to form to reach the required pressure drop to initiate the defrost cycle. The unit is defrosting far too often and wasting energy. The technician cleans the outdoor coil and tells the customer that the electrical bill should return to normal.

Service Ticket 6603

Customer Complaint: Not Enough Heat

Equipment Type: Split System Air Source Heat Pump

The technician answers a service call for a customer complaining that the home is too cold and not getting enough heat. This has only been happening within the past few days, and before that time the house was warm enough. The technician checks the thermostat settings, and they seem to be OK, but the room temperature of 65°F is considerably lower than the setpoint of 70°F. The blower for the air handler in the basement appears to be operating normally, but the temperature of the indoor coil is lower than expected and the auxiliary electric strip heaters are on.

The technician goes outside and removes the protective grille from the outdoor coil and finds it to be covered in ice. This most likely indicates a problem with the defrost cycle. The defrost system for this unit is the time-temperature type. The problem could be a loose or faulty defrost thermostat. A poor contact between the thermostat and the coil tube prevents the thermostat temperature from dropping below 26°F. However, the technician cannot check this because the entire coil is covered in ice, including the thermostat.

The technician decides to initiate the defrost cycle manually while at the same time testing the defrost timer control board. After turning off the power, a jumper is placed across the outdoor thermostat connections DFT and R (see Figure 66-17). Then turning the power back on, the heat pump immediately shifts into the defrost mode. This indicates that the defrost timer is working properly. After enough of the ice is clear, a visual inspection seems to indicate that the outdoor thermostat sensor is mounted correctly with good contact. Therefore, suspecting a faulty thermostat, the technician replaces it.

UNIT 66—REVIEW QUESTIONS

1. When a heat pump system is in the heating mode and there is an increase in the temperature rise, what does this indicate?
2. How often should throwaway filters be checked?
3. Why should automotive oil never be used to lubricate blower motors?

4. What are the three major differences between an air-conditioning and a heat pump system?
5. When changing a reversing valve, in what position should the main piston and also the pilot valve sit?
6. Why must the pilot valve be positioned as described in question 5?
7. When installing a new valve, it should be protected from getting too hot. What is the maximum temperature the valve body will tolerate?
8. What is the primary refrigeration problem in a heat pump system?
9. List four common problems with check valves on a heat pump system.
10. What are the indications a check valve has stuck closed on an outside coil?
11. Name the four most predominant defrost systems.
12. A temperature-differential defrost system will not go into defrost. This is the most common complaint on this control. Describe the correct solution to this problem.
13. A pressure-time-temperature defrost system goes into defrost with very little frost on the bottom of the coil. Describe the major cause of and solution to this problem.
14. If the unit does not run, what is the first thing to check?
15. Basically, the service problems with heat pumps fall into three main categories. What are they?
16. Why might customers complain about their heat pump systems being cold and drafty?
17. If the hot gas sensor located in the compressor discharge line shuts down the compressor, this may indicate what?
18. If the high-pressure switch located in the compressor discharge line shuts down the compressor, this may indicate what?
19. How should the accumulator for a heat pump system be sized, and why?
20. Why is it not recommended to energize the solenoid coil when it is not installed on the reversing valve?

UNIT 67

Basic Building Construction

OBJECTIVES

After completing this unit, you will be able to:

1. recognize the different materials used in basic construction and select the proper procedures and methods of construction for each.
2. describe the different insulation R values of common building materials.
3. relate the importance of fire dampers in construction.
4. incorporate the different methods of construction necessary for a successful residential or commercial project.
5. forecast what part of an HVACR system needs to be installed during each phase of construction.
6. explain the importance of LEED certification.

67.1 INTRODUCTION

The heating and air-conditioning system becomes an integral part of the building. System components, ductwork, and piping must all be supported by the structural members of the building. Wiring, ductwork, and piping must pass through floors, walls, and ceilings. An understanding of common building construction is necessary to ensure safe installations. Improperly supported equipment can pose a safety hazard. Cutting the wrong structural components of a building can compromise the integrity of the entire structure. Air-conditioning technicians must have an understanding of basic building construction so that they can intelligently discuss aspects of the building construction that will affect the installation of the HVACR system with the general contractor.

67.2 BASIC RESIDENTIAL CONSTRUCTION

There are four major parts of a residential building:

- Foundation
- Floor
- Walls
- Roof

Foundation Types

The foundation supports the rest of the building. As seen in Figure 67-1, the foundation of a residential building is generally one of three construction types:

- Slab on grade
- Crawlspace
- Basement

All foundations, regardless of type, rest on a footing. The footing supports the weight of the building, spreading it over the entire area of the footing. The footing dimensions

vary depending upon the type of soil and the local frost line. Figure 67-2 shows the cross-section of a typical footing. Most footings are poured concrete reinforced with steel reinforcing rod.

67.3 SLAB ON GRADE

Concrete slab-on-grade floors are poured on the ground with reinforcing. The reinforcing may be post tension cables, reinforcement rods, or wire mesh. These materials are used to help prevent cracking of the slab over time. Typical residential slabs are from 4 to 6 in thick and are poured continuously, incorporating the footing and crossbeams where they are used (Figure 67-3). The concrete is deeper at the footing area, and the footing reinforcing material is heavier than the reinforcing material used in the rest of the slab. Figure 67-4 shows a slab that is ready to pour.

Running Lines Under a Slab

Refrigerant lines, plumbing, and wiring must sometimes be located under a concrete slab. If refrigerant lines or condensate plumbing are to be placed below grade, they must be placed before the slab is poured. They should be installed inside a 3–4-in chase or conduit pipe. The conduit is buried in sand to protect it from sharp objects such as stones (Figure 67-5).

CAUTION

Copper piping, including refrigerant lines, reacts to concrete. Therefore, copper tubing should not be buried directly in the concrete.

When installing refrigerant lines and condensate drain lines before a slab is poured, make certain that your dimensions are taken from the outside of the building to locate these pipes. It is often the case that dimensions are given

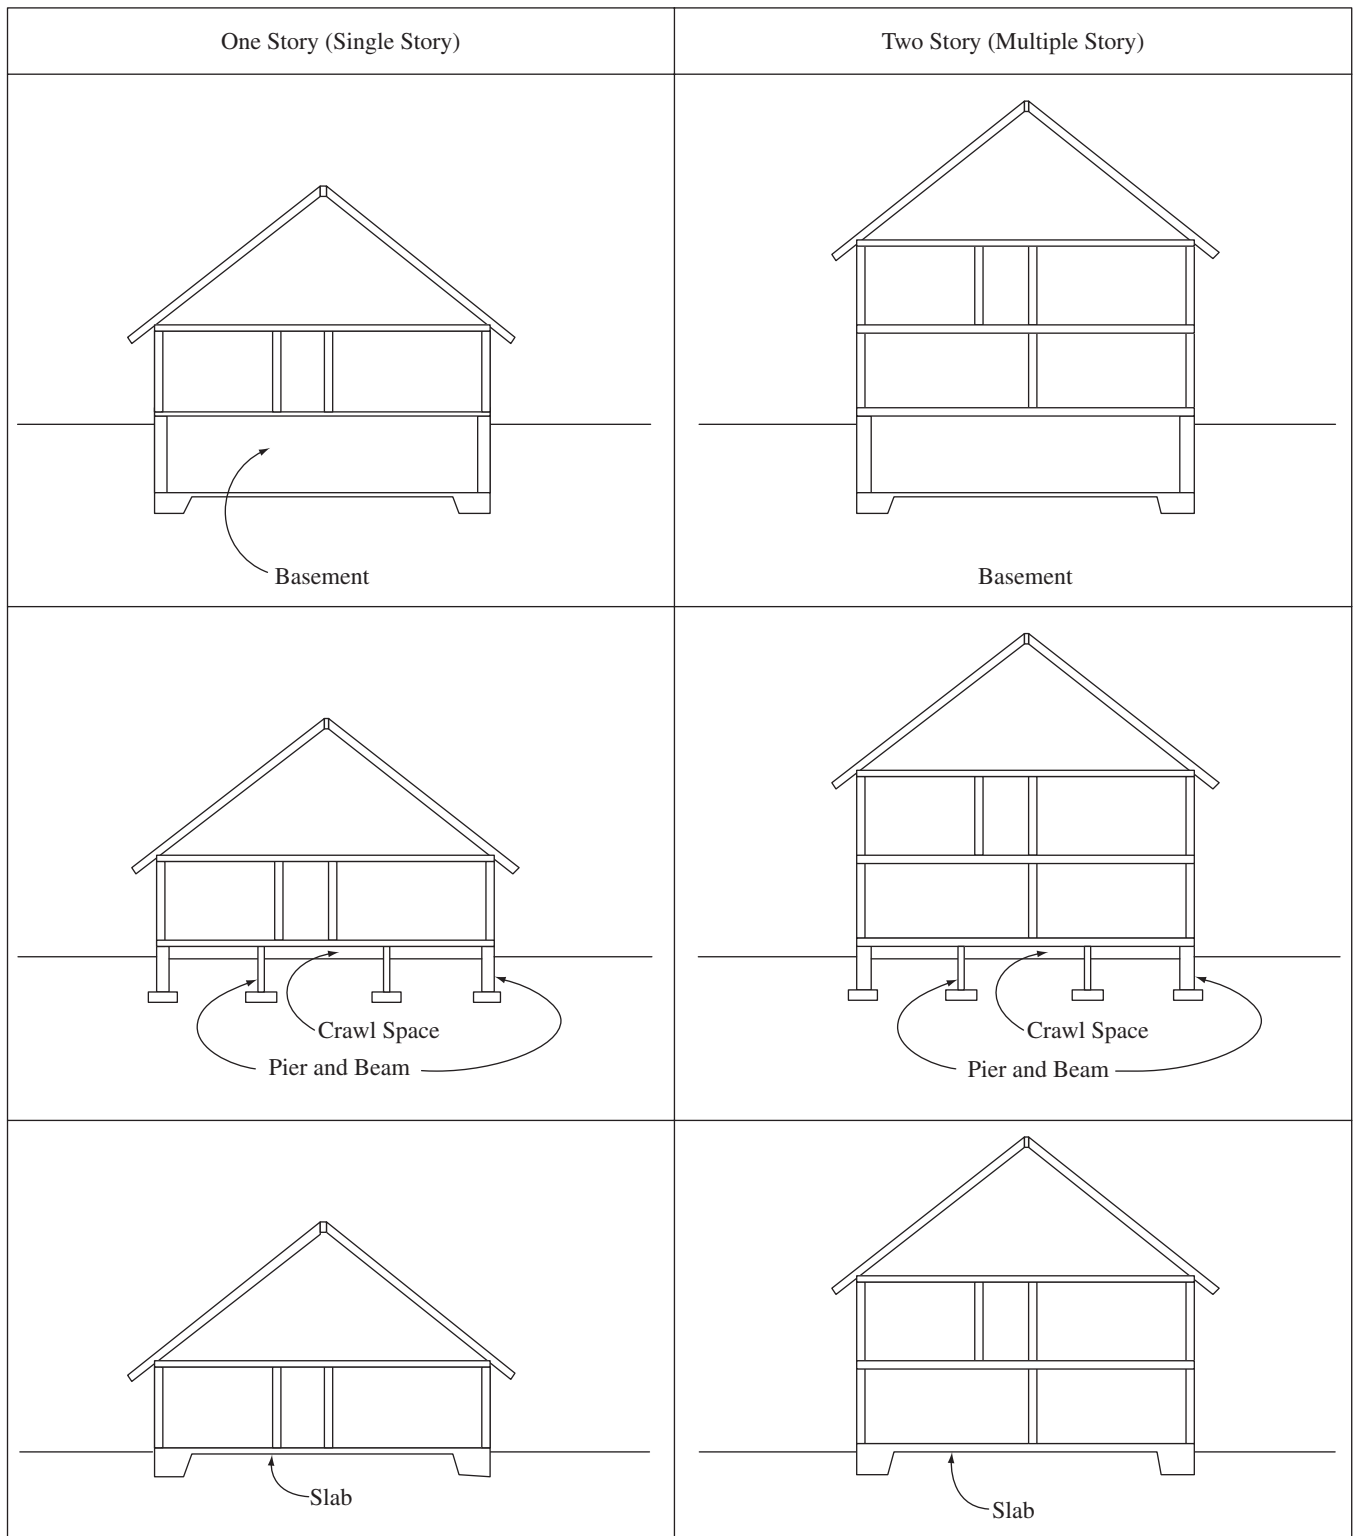

Figure 67-1 Basic house design and types of foundation used in residential construction.

from the inside wall. If the outside building dimensions are not given, you must look at the wall thickness as provided on the detailed wall section and add that dimension to your interior dimensions so that your pipes will come up in the appropriate location.

For example, in the condensate drain in the center of Figure 67-6, the center of the drain is approximately 2 in inside the air-conditioning equipment room. The distance from the outside kitchen wall to the condensate drain is calculated by adding the wall thickness and the distance

Figure 67-2 Detail of typical footing and foundation wall.

Figure 67-3 The footing and support beams are formed along with the slab.

from the equipment room wall to the drain to the 13 ft by 4 in dimension on the plan. 13 ft by 4 in + 4 in outside wall thickness + 2 in distance from equipment wall to drain = 13 ft by 10 in. The distance to be measured is 13 ft by 10 in from the outside kitchen wall.

However, this only locates one dimension. It is also necessary to determine the distance from the outside bathroom wall to the condensate line. This distance is calculated by adding the outside wall thickness to 9 ft by 0 in and then subtracting the inside wall and pipe distance inside the room.

$$9 \text{ ft by } 0 \text{ in} + 4 \text{ in outside wall} - 4 \text{ in inside wall} - 2 \text{ in distance to drain} = 8 \text{ ft by } 10 \text{ in}$$

The distance to the condensate pipe from the outside bathroom wall is 8 ft by 10 in. Always double-check your dimensions before leaving the job site after roughing in these lines. Figure 67-7 shows lines being installed in a concrete slab.

(a)

(b)

Figure 67-7 All copper lines are protected with foam insulation so that they do not come in direct contact with the slab concrete.

67.4 CRAWLSPACE FOUNDATIONS

The foundation wall rests on the footing. The floor will be constructed and supported by the foundation wall along the perimeter of the house and on beams supported by piers in the interior portion of the house (Figure 67-8). A crawlspace is an unfinished space beneath the floor that is enclosed by the foundation wall. Crawlspaces get their name from their height. Typically, most crawlspaces are too low to walk in, necessitating crawling to move from one area to another. There is no floor, just dirt. The dirt should be covered with a vapor barrier (Figure 67-9).

Figure 67-9 Crawlspace with a vapor barrier. (Courtesy of Basement Systems, Inc.)

Figure 67-8 Pier-and-beam foundation for supporting floor joists.

The wiring, plumbing, air-conditioning equipment, and ductwork are usually located in the crawlspace of houses with crawlspace construction.

TECH TIP

The vapor barrier is extremely important. Moisture accumulation under the house can create unhealthy conditions that promote mold and attack the wood members of the floor. The vapor barrier is also important for comfort. Houses with crawlspaces that lack vapor barriers can feel clammy in the summer, even at relatively cool temperatures, because of the increased humidity entering the house through the crawlspace.

67.5 BASEMENTS

Residential construction sometimes includes a basement, as shown in the drawings in Figure 67-1. Basements have a floor and are high enough to walk in. While the standard ceiling height of a normal room in a residence is 8 ft, basement ceilings may be lower. When the basement ceilings are less than 7 ft high, laying out and installing ductwork so it does not interfere with the use of the basement can be a problem. Basements are constructed in houses in many states and regions but may not be very common in other areas. Area soil conditions and the level of groundwater both affect the construction of residential basements.

Basement walls are typically constructed with poured concrete or cinderblock walls (Figure 67-10, top, middle). They usually have concrete floors. However, in some arid (dry)

Figure 67-10 Types of basement wall and floor construction techniques used for residential homes.

Figure 67-11 Typical framing is installed on 16-in centers; blocking is used at wall intersection to provide easier sheetrock installation.

climates, such as Denver, Colorado, basements may have a wooden joist floor structure (Figure 67-10, bottom). Properly designed and constructed basements provide a relatively low cost per square foot additional space to residences.

Moisture and poor ventilation are the two most common problems associated with basement areas. Without adequate dehumidification, high levels of moisture can contribute to the growth of mold and mildew. Proper ventilation can help control mold and mildew growth as well as provide better indoor air quality.

67.6 HOUSE FRAMING

Most residential construction uses wood as the primary structural material for walls, floors, ceilings, rafters, and decking material (Figure 67-11). Steel studs and beams can be used in some residential construction but are not in widespread use. Some residential structures are made of masonry materials such as concrete blocks or poured concrete walls. Typical “brick” houses are actually brick veneer; the walls are still framed. The brick wall is not structural but built in front of the frame wall and tied to it to hold the brick wall in place (Figure 67-12).

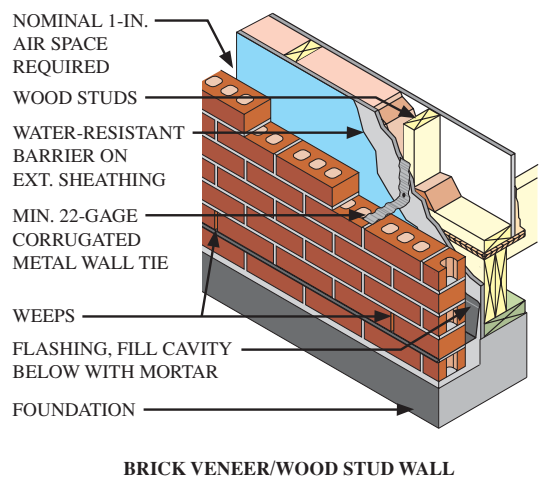

Figure 67-12 The brick veneer wall is tied to the frame structural wall.

Nominal Size	Actual Dimensions
2 × 4	1½ × 3½
2 × 6	1½ × 5½
2 × 8	1½ × 7¼
2 × 10	1½ × 9¼
2 × 12	1½ × 11¼

Figure 67-13 Lumber dimensions in inches.

Framing Members

Nearly all framing members in a traditional wood frame house are “2 by” lumber with a nominal 2-in thickness. It is rough cut at 2 in, but the actual thickness is closer to 1½ in by the time the lumber is planed. The nominal dimensions and the actual dimensions for most common framing lumber are listed in Figure 67-13.

Floor joists support the floor. They rest upon the foundation wall and on beams supported by piers. Typically, floor joists are placed 16 in on center. This means that the measurement from the center of one framing member to the center of the next one is 16 in. Floor joists vary in size from 2 × 6 up to 2 × 12 depending upon the span, the type of wood used, and the floor load. The walls are constructed of studs. Wall studs are usually 2 × 4 on 16 in centers. Ceiling joists lie on top of the walls and support the weight of the ceiling. Ceiling joists are usually 2 × 6 and are usually placed 16 in on center. Rafters rest on the exterior walls and support the roof. Rafters can be as small as 2 × 6 or as large as 2 × 12 depending upon the span, roof pitch, type of wood, and snow load.

GREEN TIP

Many contractors are using 2 × 6 wall studs on 24-in centers because the larger space formed between the inner and outer walls allows for more insulation.

67.7 WOOD FLOOR CONSTRUCTION

Floor construction for crawlspace and basement foundations is similar. Crawlspace foundations use piers and beams to support the floor joists; basement foundations can use either piers and beams or load-bearing walls to support the floor joists. Floor joists are spaced either 16 or 24 in apart. These joists can be solid wood, wood trusses, or engineered wood I-beams. Figure 67-14 shows a floor system framed with dimensional lumber. Figure 67-15 shows floor joist framing using engineered wood I-beams, and Figure 67-16 shows a floor framed with open-web wood trusses. When solid wood joists are used, any ductwork running perpendicular to the joists must be located below the joists. Open-web trusses and engineered I-beams may allow the ductwork to pass through precut or fabricated openings. With permission from the construction manager and the manufacturer of the laminated beams being used,

Figure 67-14 Dimensional lumber floor joists.

Figure 67-15 Wood I-beam floor joists.

Figure 67-16 Open-web floor joists.

(a)

(b)

Figure 67-17 Vents going through two types of floor joists: (a) truss and (b) beam.

you may be allowed to cut holes on site that will allow the ducts to pass through (Figure 67-17).

SAFETY TIP

Do not cut a hole in any structural member without first obtaining permission from the manufacturer of the product and the job site foreman. Under no circumstances can a beam's structural surface be cut, shown in red in Figure 67-18. Cuts or gouges along these surfaces can cause the structure to prematurely fail.

NEVER CUT THE EDGE OF A LOAD SUPPORTING BOARD

Figure 67-18 Cutting the edge of a horizontal supporting beam will significantly reduce the beam's strength.

Figure 67-19 Tongue-and-groove flooring material.

Flooring Material

Wood floors consist of multiple layers: a subfloor, the underlayment, and the actual flooring surface. The subfloor is commonly plywood or OSB (oriented strand board) with tongue-and-groove edges along its length (Figure 67-19). The subfloor ranges in thickness from $\frac{5}{8}$ in to $1\frac{1}{8}$ in. When $\frac{5}{8}$ -in material is used for subflooring, another layer of plywood or OSB is applied at right angles to the subfloor. This layer is called the underlayment. It normally has a smooth finish to facilitate applying the finished flooring materials. The total thickness typically must be at least 1 in. The $1\frac{1}{8}$ -in flooring material does not need an extra layer of underlayment.

Subflooring and underlayment are often glued and nailed down. Sometimes screws are used in place of nails. Using mastic increases the overall floor strength and reduces future floor squeaks. Figure 67-20 shows how the plywood decking is offset—that is, each new length starts at a different place from the one next to it so that the seams between pieces of plywood do not occur next to each other. This increases the strength and durability of the floor.

(a)

67.8 WALL CONSTRUCTION

Figure 67-21 shows the typical wall sections for the four most common types of residential wood frame construction. You will note from the first-floor construction level that each of the typical wall sections is similar.

Most residential walls are constructed with 2×4 s located 16 in on center (see Figure 67-11). In some cases, 2×6 s are used on the exterior walls. This allows for more insulation to both reduce the heat load and the sound level in the dwelling. In some areas, when 2×6 s are used in the perimeter wall, they may be spaced 24 in on center. The 2×4 s or 2×6 s used for walls are located on a horizontal board called a base plate. If this base plate is located on a concrete floor, it must be pressure-treated lumber. This is to reduce both wood rot and insect attacks. Two horizontal boards are placed on top of the stud wall. These are called the top plate. Typical wall heights for residential construction are 8 ft, 9 ft, and 10 ft, with 8 ft being the most common. Vapor barriers are frequently used in wall construction to control the flow of water vapor through the wall. The location and type of vapor barrier is in part determined by the climate. A vapor barrier is placed on the outside of the 2×4 wall in warm climates and on the inside in cold climates before the finished siding or masonry work is performed, as shown in Figure 67-22. House wraps have become popular for controlling infiltration through the wall. A house wrap is a large roll of material that can literally be wrapped around the exterior of the house before the exterior siding is installed (Figure 67-23). House wraps differ from vapor barriers in that they are specifically designed not to be a vapor barrier. They prevent air leaks through the wall without impeding the flow of water vapor.

67.9 CEILING AND ROOF CONSTRUCTION

Some builders use prefabricated roof trusses, as shown in Figure 67-24. These are almost always fabricated out of 2×4 materials with metal cleats connecting the joints. Contractors often favor such trussed roof systems

(b)

Figure 67-20 (a) Plywood decking is glued and nailed to the floor joists; (b) plywood joints.

Figure 67-21 Typical wall sections: (a) slab with siding; (b) slab with brick veneer; (c) pier-and-beam with siding; (d) pier-and-beam with brick veneer.

Figure 67-22 Vapor barrier is installed before brick veneer is applied.

Figure 67-23 House covered with house wrap to reduce infiltration.

Figure 67-24 Prefabricated trusses are available in a variety of widths.

because they are strong, durable, and easily assembled on the job site. They make it slightly more difficult for the air-conditioning technician to locate a unit in an attic and make straight duct runs.

If trusses are not used, the ceiling rafters are typically 2×6 to 2×12 dimensional lumber depending on the room span, as shown in Figure 67-25. Roof rafters are typically 2×6 s, but, depending on the height of the roof, width of the span, and possible snow load or northern climates, 2×8 , 2×10 , and even 2×12 may be used for rafters. The entire roof area will be covered by thick plywood roof decking material for composite roofs, asphalt shingles, and sheet-metal roofs. When wood shingles are used, a lapped system will be installed across the top of the rafters as opposed to roof decking. An advantage of shingle construction is that with this lapped substructure the attic area will vent freely, which reduces the heat load on the residence during summer.

Figure 67-25 Ceiling joists can be made from a variety of sizes of conventional lumber depending on the roof slope, load, and span; the flatter roof section here uses 2×6 s, but the steeper section uses 2×12 s.

SAFETY TIP

A safety harness and lanyard are required under OSHA regulation for construction workers anytime they will be working more than 6 ft above the floor.

67.10 INSULATION

There are four common types of insulation used in residential construction:

- **Rock wool** Rock wool is a synthetic material fabricated from a mineral.
- **Fiberglass** Fiberglass insulation is a spun glass. Fiberglass is available in rolls and bats with or without an attached vapor barrier. Most fiberglass bat insulation is pink or yellow. Blown-in fiberglass is usually white. The color of the insulation has no effect on the capacity of the insulation to resist heat.
- **Cellulose insulation** Cellulose insulation is a synthetically produced insulation product that uses recycled newspaper as its basic material. Cellulose insulation can either be blown loose or else a binder can be added so that it can be blown in wall cavities as a solid fill material.
- **Foam insulation** There are a number of foam insulations that can be used in residential construction as either a sheet or a product that is blown in on site.

SAFETY TIP

When working with insulation, wear a respirator to avoid breathing the fine insulation dust. Avoid touching insulation with unprotected skin. Wearing a long-sleeved shirt, gloves, and a cap will reduce your exposure to insulation that can cause irritation to your skin.

Figure 67-26 Wires that go through the top plate of a wall must be either caulked or filled with expanding foam.

For all insulation, the ability to resist the transfer of heat is directly related to its thickness. Some materials may have greater resistance per inch of material than others. However, compressing the insulation material significantly reduces its heat resistance. Squeezing a 6-in fiberglass batt into a $3\frac{1}{2}$ -in wall space will not create a superinsulated wall. Fiberglass batts designed for insulating standard $3\frac{1}{2}$ -in walls are available in R-11 and R-13 densities.

Often the 2×4 top plates and bottom plates on a wall must have holes drilled in them for wires or plumbing to pass through. These holes must be sealed to prevent air infiltration. The holes are typically filled using expandable foam, as shown in white in Figure 67-26. Any holes drilled horizontally in 2×4 wall studs are typically not sealed.

The ceiling is the area in a residence that loses and gains most of the heat. Since ceilings are so crucial for heat gain and loss, code requires that a much thicker layer of insulation be installed in the attic. Attic insulation can be blown, loose insulation, or batt insulation. Table 67-1 lists common insulating materials and their R values based on thickness.

67.11 WALLS AND CEILINGS

The most common material found on interior walls for residences is sheetrock. Sheetrock is a product that has paper on both sides of a powdered gypsum. Figure 67-27 shows a room before (a) and after (b) sheetrock installation. Sheetrock is not a structural material. If it is struck very hard, the paper will become damaged and the gypsum can be pulverized. Once sheetrock has been damaged, the damaged portion must be removed and replaced with a new section of sheetrock. Sheetrock is relatively soft and can be easily pierced with a screwdriver.

Sheetrock is attached to the stud using either sheetrock nails or screws. The sheetrock joints are covered with a sheetrock compound and paper tape. The paper tape does not have adhesive. It is held in place by the sheetrock compound. Sheetrock is finished by sanding the seams and joints and most often has a texture sprayed on as a finishing step.

Table 67-1 R Values of Common Building Materials

Material	R per Inch
Batt and blanket rock wool	R3.7
Blown cellulose	R3.1–R3.7
Blown mineral wool—horizontal fill	R2.9–R2.2
Blown mineral fiber	R2.2–R2.9
Expanded polystyrene board (white bead board)	R4.0
Fiberglass batt, high density	R3.5–R4.3
Fiberglass batt, standard density	R2.9–R3.7
High-density batt and blanket fiberglass	R4.3
Loose-fill cellulose	R3.7
Loose-fill fiberglass	R2.2
Loose-fill rockwool	R2.9
Low-density fiberglass batt and blanket	R3.1
Medium-density fiberglass batt and blanket	R3.7
Mineral wool batt	R3.14–R3.80
Polystyrene board (blue or pink board)	R6.3–R5.6
Polyurethane board (open cell)	R5.50–R6.25
Rigid foam board	R3.7–R8
Spray-on polyurethane foam	R6.3–R5.6
Spray-on cellulosic fiber	R3.4–R2.9

SAFETY TIP

Sheetrock will not support your weight. If you intentionally or accidentally step on a sheetrock ceiling, you will fall through. Pay very close attention to where you are stepping when working in an attic to avoid a fall.

67.12 CONSTRUCTION PHASES

Construction projects typically have four major phases of construction:

- Site preparation and foundation work
- Framing
- Dried in
- Exterior and interior finish work

Figure 67-28 shows these four phases in a house under construction. The site preparation phase prepares the building site, including any required excavation or grading. No air-conditioning work is done during the site

(a)

(b)

Figure 67-27 Sheetrock installation: (a) sheetrock installed on ceiling first; (b) sheetrock installed on walls with joints taped and bedded.

preparation of houses built on crawlspace and basement foundations. Placement of refrigerant lines, wiring, drain lines, and sometimes even ductwork is done during site preparation for houses built on a slab.

The framing phase is when the basic structure of the house is erected. Roughing in the duct system starts at the end of the framing phase. Roughing in a system includes making any cuts in the structure for ducts to pass through, locating return-air boxes, and locating boots for supply registers. Rough-in typically continues into the dried-in phase. It is important to get the boots roughed in before the sheetrock is installed.

A house is dried in when it is weatherproof. At this point it has a roof, exterior walls, windows, and doors. Typically most of the air-conditioning installation is performed after the house is dried in. This includes setting the equipment, pulling the control and power wires for the equipment, running the refrigerant lines, and running the ductwork.

Most of the air-conditioning work should be completed before the interior finish work is done. Typically, the supply-air registers and return-air grilles are installed after the walls have been painted. The thermostat is also usually not installed until after the walls are painted. The final wiring and commissioning of the system takes place toward the end of the finishing phase.

Figure 67-28 Major steps in house construction: (a) site preparation; (b) framing; (c) dried in; (d) exterior flat work.

67.13 LIGHT COMMERCIAL CONSTRUCTION

Buildings constructed for light commercial use may either be built in a fashion similar to residential, with all wood construction, or they may be constructed using metal studs and steel structures. When wooden structures are used, the construction of commercial buildings is very similar to residential construction.

Fire codes often require light commercial buildings to be constructed using metal studs (Figure 67-29). Metal studs are preformed out of 16-, 18-, or 20-gauge galvanized sheet metal and are assembled using sheet-metal screws.

Figure 67-29 Typical metal stud wall layout with door opening.

67.14 FLAT ROOFS

Commercial buildings often have flat roofs. A flat roof is constructed with a roof decking that may be either sheet metal or wood. Sheet-metal decking is often covered with a thin layer of lightweight concrete. Insulating board is placed on this deck and the top surface is then sealed using hot tar, thin layers of roofing paper, or rubber roofing material layered in sheets and glued together. Usually a thin layer of gravel is applied to the top surface. A roof with a layer of gravel will stay cooler because the gravel reflects a lot of the heat.

When rooftop air-conditioning units are used, a curb must be first put in place on the roof and sealed completely. A roof curb is a raised metal frame that rooftop air conditioners rest on. The curb is sealed to the roof along the outside and has holes in the inside to allow ductwork to pass through. Curbs are typically installed by a roofing contractor. Water leaks are a constant potential problem for flat roofs, and it is essential that these air conditioning curbs be sealed completely and properly. Water leaks are such an ongoing issue for flat roofs that many, such as the one pictured in Figure 67-30, are bonded. Bonding is insurance that the roofing contractor provides the building owner to cover water damage if the roof were to leak. Because of this insurance bond provided by the roofing contractor, it is essential that anytime air-conditioning work is being performed that would require a new opening to be cut through the roof, the roofing contractor be contacted before the work begins. This must be done whether the hole is for electrical, refrigerant lines, or the installation of a new rooftop unit. Failure to contact the roofing contractor may result in your air-conditioning company being held liable for any water leaks that occur in the building.

Figure 67-30 Rooftop unit on a composite flat roof.

SAFETY TIP

A roof's slope is given as its height in inches as compared to each 12 in of horizontal run. Roofs that have slopes less than 8 in for each 12 in can be worked on relatively safely. Roofs that have slopes greater than 8 in are very hard to impossible to stand on without slipping. If you must work on a sloped roof, you must wear a safety harness.

67.15 DROPPED CEILINGS

Dropped ceilings are commonly used in light commercial buildings. They allow for easy reconfiguring of the interior space as the business changes. Dropped ceilings are constructed by suspending a grid of metal rails. Ceiling tiles are placed in the grid from above. These tiles are easily damaged, so be very careful if you must move them. Do so with clean hands, and be very careful not to scar or scratch the surface of the tile. If the tile becomes damaged, you may have difficulty locating an exact replacement pattern, which can become time-consuming and expensive. Often the space above a building's dropped ceiling is used as the return-air plenum for light commercial buildings.

SAFETY TIP

Dropped-ceiling grids will only support the ceiling! They will not support equipment, refrigeration lines, ductwork, wiring, or you.

67.16 WALLS AND PARTITIONS

Walls and partitions are similar in commercial construction. Walls, however, extend all the way up through the ceiling to the roof of the building. Partitions only extend up to the ceiling. That makes partitions very easy to move as the business reconfigures as it grows. Some walls extend

Figure 67-31 Partitions in commercial construction are often used as room dividers and do not extend beyond the dropped ceiling; because partitions are not structural, automatic fire dampers are not required when a duct passes over or through partitions; automatic fire dampers are required anytime a duct passes through an interior wall.

all the way up to the ceiling and are classified as firewalls. These walls are constructed with fire-resistant materials. Building and fire codes regulate the construction of firewalls. Anytime supply or return ducts must pass through a firewall, the duct must have a fire damper (Figure 67-31). Fire dampers will automatically close, sealing off the duct to prevent the spread of smoke and fire throughout the building.

67.17 GREEN BUILDING

Green building is a general term used to indicate construction techniques and designs that minimize energy use and reduce water consumption, waste, and a building's impact on the environment. The increased demand for energy, water, and land resources has moved a number of professionals in the construction industry to look for ways of building that use these resources more than intelligently. Rather than simply trying to find more energy and water, they seek ways to use less of these precious resources through design that looks at the entire cost of a building, including its operation. The cost of owning a green building is no more than, and often less than, a traditionally constructed building. Figure 67-32 compares the construction, finance, and operating costs of two comparable homes, one built to code, the other built to incorporate green building principles. Although the green home cost more to build, it costs no more to own because it costs much less to operate.

U.S. Green Building Council

The USGBC is a 501(c)(3) nonprofit community of leaders working to make green buildings accessible to everyone within a generation. A major part of their work involves establishing standards to encourage green building. They have developed the Leadership in Energy

Comparison	Standard Construction (\$)	LEED Construction (\$)	Cost Difference (\$)
Initial price	300,000	308,500	+ 8,500
Mortgage	1,890	1,945	+ 55
Energy bill	150	105	–45
Water bill	30	20	–10
Net ownership cost	2,070	2,070	Same

Figure 67-33 Green fact sheet for a LEED-certified building.

Efficiency and Environmental Design (LEED) program to certify green building standards. Figure 67-33 shows the “green facts” of LEED-certified buildings. Studies have shown that LEED certified buildings cost less to own and operate over their lifetime. This has gotten the attention of people whose only interest in LEED construction is financial; they have discovered that building green saves money.

Air Conditioning and LEED Certification

Heating and air conditioning account for approximately half of a building’s energy use. A major part of LEED certification is reducing a building’s overall energy use. The building’s air-conditioning system can have a major impact on LEED certification because it represents such a large portion of the building’s energy use. Energy-efficient equipment is only part of the answer. The equipment must be properly applied and installed. Air-conditioning technicians can be part of the green wave by ensuring that systems are properly applied, installed, and serviced. Bad installation and poor service will keep even the most energy-efficient equipment from being green.

UNIT 67—SUMMARY

The construction techniques used in different regions of the country vary. In some areas of the country, basements are commonly found in residential construction, while in other parts of the country, most residential construction is built on concrete slabs. However, the basics of construction remain the same throughout the country.

Construction usually progresses through four phases: site and foundation preparation, framing, drying in, and interior and exterior finish work. Concrete slabs, crawlspaces, and basements are three common foundation systems. Regardless of the foundation system, all foundations rest on a footing.

Wood framing is the most common structural system used in residential construction. Floor joists can be made of lumber, open-web wood trusses, or engineered wood I-beams. Walls are typically constructed of 2 × 4 studs placed 16 in on center. Ceilings and roofs can either be framed with joists and rafters or with roof trusses.

Insulation is especially important in reducing the heating and cooling load of the structure.

Light commercial and residential construction techniques are similar. Commercial construction often uses large steel and concrete beams, but much of the interior finish and detail work is similar to light commercial. Therefore, understanding the basic construction techniques for light commercial can help with commercial jobs.

WORK ORDERS

Service Ticket 6701

Equipment Type: New Split-System Installation in House on Concrete Slab

In the site preparation phase, the general contractor is preparing a slab to be poured and needs any work under the slab to be completed. Refrigerant lines and the condensate drain need to be installed.

The technician arrives at the job site, lays out the location of furnace/AHU and also the location of condensing unit, and runs a 4-in PVC conduit under the future concrete slab. The technician then rolls out both the suction and liquid lines, insulates the suction line, and pulls them along with thermostat wire inside the conduit, being careful not to kink the copper tube or tear the insulation. The technician checks to make sure there is no place where concrete from the poured slab

will contact any part of either line and makes sure there is plenty of tubing length on each end to connect the furnace/AHU and the condensing unit. The technician makes sure that the tubing caps remain in place on each end of the tubing so the system will be free of moisture and foreign matter. Before leaving, the technician takes location dimensions of the line location and records this on the blueprints. The job is ready for slab inspection.

Service Ticket 6702

Equipment Type: New Split-System Installation in House on Concrete Slab

In the framing phase, the general contractor calls and the framing is near completion. The ductwork and wiring need to be roughed in. The refrigerant lines were pulled during the slab preparation.

The technician roughs in the return-air box in the hall and the supply-air drops in the ceiling. The control wiring is run from the thermostat location in the hall to the air handler in the equipment closet. The control wiring between the air handler and the condenser was run with the refrigerant lines during slab preparation. The electrician pulls the power wire for the air handler inside and the condensing unit outside. The technician installs nail plates where appropriate. The technician then calls for a rough-in inspection.

Service Ticket 6703

Equipment Type: New Split-System Installation in House on Concrete Slab

The general contractor notifies the technician that the house is dried in. It is time to set the equipment, run the ductwork, connect the refrigerant lines, and complete the wiring.

The technician sets the air-handling unit in the equipment closet and the condensing unit on the pad outside. The refrigerant lines are connected to the air-handling unit. The condensate line is run from the air-handling unit to the condensate stub provided during slab preparation. The electrician wires the power wire to the air handler and the condensing unit. The technician wires the low-voltage thermostat wiring to the air handler and condensing unit.

The return- and supply-air plenums are installed, and the ductwork is run. The supply duct is run in the attic and the return runs to a return box in the hall. Since the supply duct is in the attic, duct with an insulation value of R-8 is used. The return duct is insulated with R-6 because it is not exposed to attic conditions. All ductwork is properly connected, sealed, and supported to prevent air leaks and restrictions.

Service Ticket 6704

Equipment Type: New Split-System Installation with Lines Under Concrete Slab

The home is complete and the new owner is ready to move in. The technician is called to do the initial system

start-up. The technician leak checks the lines and coil using nitrogen. Finding no leaks, the lines and coil are evacuated. While the system is being evacuated, the technician checks all electrical connections. With the disconnect remaining off, the voltage to the lugs at the top of the disconnect is checked and compared to the voltage on the system data plate. The thermostat is mounted and wired. The system is valved off when the vacuum reaches 400 microns. The vacuum holds for 10 minutes, rising slightly to 450 microns and leveling off. After determining the system is tight, clean, and dry, the technician releases the refrigerant from the condenser into the system. The technician checks the voltage before starting the unit, starts the unit, and then checks the voltage again after starting the unit to check for voltage drop in the power wire. The information in the manufacturer's installation instructions is used to check the system charge. The technician records the system operating data on the start-up form used by the company. The technician calls for final inspection when the system is performing per the manufacturer's specifications.

UNIT 67—REVIEW QUESTIONS

1. What is the standard ceiling height in a residence?
2. Name the two most common problems with basements.
3. Name the reinforcement materials used in concrete slabs.
4. Why should refrigerant lines or condensate plumbing be installed in a chase or conduit if they are to be under a poured concrete slab?
5. How is ductwork location affected by solid wood floor joists?
6. Why is plywood decking offset, as seen in Figure 67-20b?
7. Why do contractors often favor a trussed roof system?
8. Name four common types of insulation used in residential construction.
9. Using Table 67-1, what would be the insulation R-factor of 4 in of medium-density fiberglass batt and blanket material?
10. What is the most common material used for interior walls of residences?
11. What material is sometimes required by the fire code for studs?
12. What is a roof curb?
13. What consequences can result from failing to contact the roofing company before making a roof penetration on a bonded roof?
14. What is the space above the drop-in ceiling in a commercial building used for in the HVAC industry?
15. What must be included in any duct that passes through a firewall?
16. What is the purpose of a fire damper?
17. Why is the cost of owning a "green" building often less than the cost of owning a conventionally constructed building?
18. What is the mission of the USGBC?
19. What does LEED certification mean?

UNIT 68

Green Buildings and Systems

OBJECTIVES

After completing this unit, you will be able to:

1. describe how the term *sustainability* applies to green building design.
2. recognize the difference between green building standards, codes, and rating systems.
3. explain the basic concept behind the LEED rating system and understand the process required to earn LEED credentials.
4. determine which codes or standards may apply for a given project.
5. describe what type of site-selection, material-selection, and system-design components satisfy the requirements for commercial and residential green building certification.

68.1 INTRODUCTION

The U.S. Department of Energy (DOE) reports that buildings use more energy than any other sector of the U.S. economy. The combined impact of all buildings, both commercial and residential, accounts for more than 70 percent of all electricity usage and 50 percent of all natural gas usage. According to the U.S. Green Building Council (USGBC), buildings in the United States are responsible for 39 percent of CO₂ emissions, 40 percent of the total energy consumption, and 13 percent of all water consumption.

“Green” construction practices are being used today that efficiently use energy, reduce waste and pollution, and create a healthy environment for the occupants. As an example the main goal of the DOE’s Building Technologies Program (BTP) is to develop affordable, energy-efficient homes by 2020 and high-performance commercial buildings by 2025. These high-performance buildings will be 60 to 70 percent more energy efficient than today’s typical buildings.

The HVACR industry must also adjust to meet the demands of government programs and regulations as they slowly develop and become mandatory. There will be increasingly stringent regulations regarding energy efficiency, alternative energy use, water conservation, and environmentally friendly building materials. As of January 1, 2011, California became the first state to develop a mandatory green building standards code (CALGreen Code) that applies to most all-new building design and construction.

in Title 24 of the California Code of Regulations and is also known as the CALGreen Code. In short, the code is established to reduce construction waste, make buildings more efficient in the use of materials and energy, and reduce environmental impact during and after construction.

68.2 SUSTAINABILITY

Sustainability is a term often used when describing green technology and innovative building design. For a building to be sustainable, it must be designed and built to meet the needs of society in ways that can continue indefinitely into the future without damaging or depleting natural resources. These buildings are designed to be energy smart and minimize electrical power consumption. High-performance buildings are able to generate their own power, and some can also supply power back to the utility grid. Not only do green buildings use fewer resources through improved energy and water efficiency, but studies have shown that they also offer a better place to live and work due to better air quality and access to natural daylight. People care about these health impacts, and so from a financial perspective, owners of sustainably managed buildings expect a higher return on investment because of the greater productivity, satisfaction, health, and well-being of the buildings occupants.

CODE

The 2010 California Green Building Standards Code, which took effect on January 1, 2011, is a code with mandatory requirements for new residential and non-residential buildings (including buildings for retail, office, public schools, and hospitals) throughout California. The code is Part 11 of the California Building Standards Code

68.3 BUILDING ENERGY CODES

Energy efficiency for a home, factory, or office building is often determined by decisions made at the time of initial construction. Choosing less energy-efficient methods and materials may save money at the outset, but this will most likely result in increased energy costs for many years to come. Energy codes and standards set minimum requirements for energy-efficient design and construction for new

and renovated buildings that impact energy use and emissions for the life of the building. Most often these standards set mandatory requirements that can be enforced. Because it is difficult to impossible to incorporate some forms of building efficiency after construction, incorporating sustainable features at the outset makes sense. Economically, it is less expensive to incorporate sustainable features during new construction than to try and add them later. The benefits of more efficient construction today are enjoyed for thirty to fifty years into the future.

68.4 GREEN BUILDING RATING SYSTEMS

Green building rating systems typically accumulate overall point totals based on factors such as energy savings, accessibility to mass transit, reductions in storm-water runoff, and a host of prevailing factors that result in maximum sustainability. The higher the overall point total, the more sustainable the building rating. These rating systems have been mostly voluntary and until recently have not been enforced as mandatory requirements. They often provide a limited number of prerequisites with many optional credits to allow more focus on the green building aspects deemed important to the user of the system. One recognized rating system is LEED (Leadership in Energy and Environmental Design). This system was created by the U.S. Green Building Council (USGBC).

CODE

Standards and codes are typically mandatory requirements that must be followed. These requirements can be addressed at federal, state, and local levels (city codes). Local codes are often referred to as jurisdictional codes. Rating systems are different in that they are not necessarily mandatory but can often be voluntary. However, the rating systems are often based upon codes and standards. Green building codes and green rating systems are somewhat unique in that they have been developed with mutual cooperation between standards organizations and rating agencies.

USGBC

The U.S. Green Building Council (USGBC) was founded in 1993, and its membership includes corporations, builders, universities, government agencies, and other nonprofit organizations. USGBC is committed to a prosperous and sustainable future through cost-efficient and energy-saving green buildings. The USGBC introduced the LEED rating system into the marketplace in 2000 and by 2010 had a total footprint of certified commercial projects that surpassed 1 billion ft². Over 36,000 commercial projects and 38,000 single-family homes have participated in LEED. USGBC is also a cooperating sponsor in the development of the two primary baseline building energy codes: ANSI/ASHRAE/USGBC/IES Standard 189.1-2009 and the International Green Construction Code (IGCC).

CODE

The IGCC integrates with the existing family of I-Codes to ensure that building designers, contractors, owners, and inspectors all work from a common platform. The IGCC acts as an overlay on other existing codes, including the provisions of the International Energy Conservation Code (IECC) as a baseline.

68.5 INTERNATIONAL GREEN CONSTRUCTION CODE (IGCC)

The International Green Construction Code (IGCC) was introduced by the International Code Council (ICC) in 2010. This is a first-of-its-kind collaboration with cooperating sponsors that include the American Institute of Architects (AIA), the American Society for Testing and Materials (ASTM International), ASHRAE, USGBC, and the Illuminating Engineering Society (IES). The IGCC provides a comprehensive set of requirements intended to reduce the negative impact of buildings on the natural environment.

The IGCC is intended to be used by manufacturers, design professionals, and contractors, but unlike voluntary ratings systems, it is written in mandatory language. The model code language becomes law when it is adopted by the appropriate state or local authority. To this point, voluntary programs have been the driving force for green construction. The IGCC has been designed to complement these programs as well as to be applied to construction projects that are unlikely to adopt the voluntary programs.

Many building rating systems offer many choices to the owner and designer but do not require increased performance in specific areas such as energy, water, natural resources, or material conservation, which may be of importance to the local jurisdiction. The IGCC is composed primarily of mandatory requirements but also allows local jurisdictions to regulate owner/designer choices for a minimum number of project electives. This allows the IGCC to produce more predictable results that are closely aligned with the local jurisdiction's requirements.

International Code Council (ICC)

The ICC is a U.S.-based nonprofit, nongovernmental membership association dedicated to building safety, fire prevention, and energy efficiency. The International Codes, or I-Codes, published by the ICC, provide minimum safeguards for people at home, at school, and in the workplace. Most U.S. cities, counties, and states adopt the building safety codes developed by the ICC.

American Institute of Architects (AIA)

AIA has been the leading professional membership association for licensed architects, emerging professionals, and allied partners since 1857.

ASTM International

ASTM International is one of the largest voluntary standards-development organizations in the world. Today, some twelve

thousand ASTM standards are used around the world to improve product quality, enhance safety, facilitate market access and trade, and build consumer confidence.

Illuminating Engineering Society of North America (IES)

The IES is the recognized technical authority on illumination. For over one hundred years, its objective has been to communicate information on all aspects of good lighting practices to its members, to the lighting community, and to consumers, through a variety of programs, publications, and services.

ASHRAE

American Society of Heating, Refrigerating and Air-Conditioning Engineers (ASHRAE), founded in 1894, is an international organization of fifty-one thousand persons. ASHRAE fulfills its mission of advancing heating, ventilation, air conditioning, and refrigeration to serve humanity and promote a sustainable world through research, standards writing, publishing, and continuing education.

CODE

ANSI/ASHRAE/USGBC/IES Standard 189.1-2009 addresses the same building spaces as ANSI/ASHRAE/IESNA Standard 90.1-2007 except with a calculated 27 percent increase in energy savings.

68.6 ANSI/ASHRAE/USGBC/IES STANDARD 189.1-2009

Standard 189.1-2009 (Standard for the Design of High-Performance Green Buildings Except Low-Rise Residential Buildings) covers site sustainability, water-use efficiency, energy efficiency, indoor environmental quality, and the building's impact on the atmosphere, materials and resources. The standard is not intended to be a design guide or a rating system, but it is expected that voluntary building rating systems will integrate this standard into their programs. The standard is based on the mandatory requirements that establish baseline criteria for a high-performance green building, and as such, these standards must be met to guarantee compliance.

American National Standards Institute (ANSI)

ANSI is a private, nonprofit membership organization founded in 1918. Its primary goal is to promote and facilitate voluntary consensus standards and conformity assessment systems. ANSI serves as an administrator and coordinator of the U.S. private-sector voluntary standardization system. Accreditation by ANSI signifies that the procedures used to create new standards meet the Institute's essential requirements for openness, balance, consensus, and due process.

CODE

ANSI/ASHRAE/USGBC/IES Standard 189.1-2009 is a jurisdictional compliance option to the International Green Construction Code (IGCC). IGCC Section 302.1 and Table 302.1 provide the framework that allows the jurisdiction to select Standard 189.1 as a compliance option.

68.7 NATIONAL GREEN BUILDING STANDARD

In 2007, the National Association of Home Builders (NAHB) and the ICC partnered to establish the National Green Building Standard. This standard applies to all residential construction work—including single-family homes, apartments and condos, land development, and remodeling renovations—and is approved by the ANSI. This standard provides homebuilders and remodelers with a third-party rating system that they can use to achieve green certification under NAHB Green and the National Green Building Certification Program.

The standard offers green building practices in six categories: lot design, resource efficiency, energy efficiency, water efficiency, indoor environmental quality, and operation maintenance. To achieve green certification, a project must have minimum point total score. Certification levels are based on progressively higher point totals and can be awarded as bronze, silver, gold, or emerald.

National Association of Home Builders (NAHB)

The NAHB is a trade association that helps to promote policies that make housing a national priority. Its primary goal is to provide and expand opportunities for all consumers to have safe, decent, and affordable housing. The NAHB has been serving its members, the housing industry, and the public at large since 1942.

68.8 ANSI/GBI 01-2010 STANDARD

The Green Building Assessment Protocol for Commercial Buildings is an assessment rating system for new construction formally approved in 2010. This standard was derived from the Canadian Green Globes environmental assessment and rating system. There are seven areas of assessment that are awarded points: project management, site, water, energy, emissions, indoor environment, and resources. There are minimum point requirements in each of the seven areas, and the level of achievement for certification range from 1 to 4.

Green Building Initiative

The Green Building Initiative (GBI) is a not-for-profit organization whose mission is to accelerate the adoption of building practices that result in energy-efficient, healthier, and environmentally sustainable buildings by promoting credible and practical green building approaches for residential and

commercial construction. The GBI is governed by a multi-stakeholder board of fifteen directors featuring representatives from industry.

68.9 DOE BUILDING TECHNOLOGIES PROGRAM (BTP)

The Department of Energy's Building Technology Program (BTP) is a partnership with the building industry to research, develop, and deploy energy-efficient building technologies and practices. BTP is working with organizations such as ASHRAE and ICC to achieve a 30 percent energy improvement in commercial and residential building codes in the United States. Another BTP initiative is to promote and support the ENERGY STAR program to ensure that appliance and equipment standards are met in terms of energy efficiency. BTP is also actively educating homeowners, builders, and developers about the benefits of embracing energy-efficient technologies and practices.

ENERGY STAR

ENERGY STAR is a joint program of the U.S. Environmental Protection Agency and the U.S. Department of Energy designed to save consumers money and protect the environment through energy-efficient products and practices. This program helped to save enough energy in 2009 to avoid greenhouse gas emissions equivalent to those from 30 million cars, while saving American consumers nearly \$17 billion on their utility bills.

68.10 LEADERSHIP IN ENERGY AND ENVIRONMENTAL DESIGN (LEED)

The LEED standards are developed by the USBGC, while the Green Building Certification Institute (GBCI) runs the LEED Building Certification. LEED recognizes five areas of performance: site, water, energy, materials, and indoor environmental quality. The LEED rating systems are grouped into five main categories: Building Design & Construction, Interior Design and Construction, Operations & Maintenance, Homes, and Neighborhood Development. To achieve LEED certification, a project must have minimum point total score. Certification levels are based on progressively higher point totals and can be awarded as certified, silver, gold, or platinum.

First Category: Green Building Design & Construction

- LEED for New Construction
- LEED for Core & Shell
- LEED for Schools
- LEED for Healthcare
- LEED for Retail

Second Category: Green Interior Design & Construction

- LEED for Commercial Interiors
- LEED for Retail Interiors

Third Category: Green Building Operations & Maintenance

- LEED for Existing Buildings
- LEED for Existing Schools

Fourth Category: Single- & Multi-family Residential Homes

LEED for Homes Three Stories or Fewer

Fifth Category: Neighborhood Design

LEED for Neighborhood Development

LEED Credentialing

The LEED professional credentials and exams are administered by the GBCI. As of May 2009, the new credentialing system is broken into three tiers. The only Tier I credential available is the LEED Green Associate. This can be earned by candidates who demonstrate that they possess the knowledge and skill to support green design, construction, and operations. The candidates must also successfully pass the two-hour LEED Green Associate exam.

There are five different credentials for Tier II, LEED AP with Specialty. The LEED AP with Specialty credential signifies an advanced depth of knowledge in green building practices. Two-hour specialty exams are available for each of the five major categories of LEED. Only one of the five specialty exams must be passed for the LEED AP credential. Candidates for the Tier III LEED AP Fellow must be nominated by their peers and have at least ten years of experience in the green building field with a minimum of eight cumulative years as LEED AP.

68.11 PLATINUM LEED COMMERCIAL APPLICATION: HANNAFORD SUPERMARKET & PHARMACY

Hannaford Supermarket & Pharmacy, located in Augusta, Maine, was recognized by the USGBC in 2009 as the first supermarket in the world to receive a LEED Platinum certification (Figure 68-1). The supermarket's 50,000-square-foot building is designed to use about 50 percent less energy than a conventional building of the same size.

Site Development

This was not a new site, as the building was constructed on the grounds of a former high school. The existing site was demolished and 96 percent of the existing building debris and contents were either recycled or reused (Figure 68-2). Parking spaces close to the store entrance are reserved for van pools and low-emission hybrid vehicles. There are

Figure 68-1 Exterior of a "green" supermarket.

Figure 68-2 Learning center that describes the benefits of recycling.

carpool spaces for employees and conveniently located bicycle racks. Reflective material on the surface of the parking lot has been designed to reduce heat-island effects.

Water

The building has a 7,000 square feet of vegetated roof comprising a mixture of green and red sedums (Figure 68-3). This “green roof” reduces water runoff, helps to insulate the store, and reclaims green space.

(a)

(b)

Figure 68-3 (a) Vegetated roof; (b) Vegetated roof and skylights.

Figure 68-4 41-kW rooftop solar panel array.

To conserve on water usage, the restrooms utilize low-flow faucets and low-flow, dual-flush toilets. The urinals are the waterless type. The seafood department uses ice-free cases. It is estimated that this combined conservation effort reduces water usage by 38 percent, equating to a savings of roughly a half million gallons of water annually.

Energy

The supermarket has been designed to use 50 percent less energy than a typical grocery store. With conventional supermarket design, the refrigeration system consumes the most electricity, followed next by lighting and then HVAC. To supplement the store’s energy supply, there is a 41-kW solar photovoltaic system located on the roof, which provides on-site power (Figure 68-4).

To reduce energy consumption, a high-performance Green Chill refrigeration system is employed at the store. The Green Chill heat-reclaim system meets almost 100 percent of the store’s heating needs by capturing the heat from the coolers, which is then used to warm the store (Figure 68-5). In addition, there are two geothermal wells located 750 feet below the ground that help to regulate the store’s interior temperature year round (Figure 68-6). Radiant heat is used to warm the concrete floors in the checkout areas and to melt snow at the outside sidewalk entrance to the store.

The building was designed to take advantage of natural lighting with an array of fifty skylights, a dozen solar tubes, large windows, and transom glass on three walls (Figure 68-7). Located in the ceiling near the center of the building is a panorama of windows designed to direct the incoming

Figure 68-5 Heat-reclaim piping.

Figure 68-8 Inside view of illumination from fabric light shelves and glass pavilion located in the center of the store.

sunlight onto fabric-covered shelves that reflect the light back toward the center of the ceiling for improved illumination (Figure 68-8). High-efficiency fixtures that come on and off automatically depending on the amount of natural sunlight entering the building are used for the interior lighting (Figure 68-9). In this way, when the sunlight is at its maximum, much of the electric lighting in the store is automatically turned off to save energy.

Conventional supermarkets often have an assortment of open freezers and cold cases to allow easy access to the product. However, new energy-efficient designs restrict the use of open cases and use mostly closed cases with glass doors (Figure 68-10). Many are equipped with motion sensors that allow LED lighting to turn on when someone approaches (Figure 68-11). The lighting then turns off again automatically when motion is no longer detected as another means to conserve power.

Materials and Resources

Over 70 percent of the wood used in the store is Forest Stewardship Council (FSC) certified. The FSC sets forth principles, criteria, and standards that span economic, social, and environmental concerns for guiding forest management toward sustainable outcomes. The interior finishes are low in volatile organic compounds (VOC). VOCs are both man-made and naturally occurring organic chemical compounds that can affect the environment and human health. Recycled

materials have been used for the store's interior surfaces, such as the pharmacy's counters. There is ongoing education awareness for recycling materials, and a storewide program is in place for recycling cardboard, plastics, paper, lightbulbs, and batteries that is also made available for customers.

Indoor Environmental Quality

The maximized natural lighting provides for a bright and cheery atmosphere that promotes customer satisfaction (Figure 68-12). The glass doors for the freezers and cold cases not only save energy but also maintain a more comfortable indoor temperature for the shoppers. The combination of a low-VOC interior and increased airflow reduces airborne contaminants (Figure 68-13). At the entrance to the store, a large informational display was built to help

take a deep breath

Such a simple thing, fresh air – but we've thought a lot about it... We ditched materials made with a higher percentage of potentially airborne chemicals in favor of safer, friendlier alternatives, at the same time maximizing airflow and ventilation in our store... no stale air here.

educate customers and employees about “green” building practices to promote a public awareness (Figure 68-14).

68.12 PLATINUM LEED RESIDENTIAL APPLICATION: BRIGHTBUILT BARN

The BrightBuilt Barn is a Platinum LEED-certified, 700-square-foot, single-story residence and loft that was built in 2008 (Figure 68-15). It is one of the few buildings in the world

Figure 68-15 Exterior entrance view of the BrightBuilt Barn.

Figure 68-16 View of the 6-kW solar panel array located on the roof.

designed to be truly carbon neutral. This is because on a typical sunny day, the Barn produces more renewable energy in the form of electricity than it uses. This additional electricity is fed back to the utility grid and acts as an offset to the carbon footprint that resulted from its initial building phase. Over time, this surplus energy will balance the carbon dioxide released directly into the atmosphere during construction and the carbon indirectly attributed to the building materials.

Guiding Principles

The five guiding principles integrated into the project from its conception are livability, sustainability, replicability/affordability, disentanglement, and education. In terms of livability, the building needed to be comfortable, functional, and attractive. Long-term sustainability for the future is achieved by reducing the carbon footprint used to create the structure. Replicability and affordability result from the Barn being built as a prototype so that others can duplicate the design to the extent that is economical for them. Disentanglement helps to provide for adaptability, allowing the building to be changed over time. Education is provided to the greater community through regularly scheduled open houses that allow others to study and learn from the project.

Design Features

The Barn features a 6-kW photovoltaic panel array located on its roof (Figure 68-16). This array comprises thirty individual 32×62 -inch solar panels able to produce approximately 20 kWh per day (Figure 68-17). The electrical use

Figure 68-17 Close-up view of 32×62 -inch solar panels.

Figure 68-18 A solar panel array's electricity-tracking monitor.

is continuously monitored by a SunPower Monitor (Figure 68-18) and can be tracked on the BrightBuilt Barn Web site. The Barn generally produces more electricity than it uses. High-efficiency LED lighting is strategically positioned throughout the building for the best illuminating effect (Figure 68-19).

The roof and walls are made from structural insulated panels (SIP). These panels are designed to form a complete

(a)

wall system that eliminates air infiltration. This superinsulated building envelope has a continuous R-40 value. In addition to the triple-glazed windows, there are light-transmitting, nano-gel-filled polycarbonate panels that impart an effect of a semi-transparent wall. These panels offer an abundance of light but provide twice the insulation value (R-12) as compared to the triple-glazed windows alone (Figure 68-20).

To provide for disentanglement, the Barn is designed so that the systems are separated physically from the structure. Electrical and mechanical systems are run through integral chassis hidden in the baseboard rather than being located in the walls themselves (Figure 68-21). Interior walls can be easily moved as future use of the building changes (Figure 68-22).

The mechanical/storage loft holds an insulated solar storage tank for domestic hot water, the heat pump air handler, and a heat-recovery ventilator. The hot-water storage tank is heated by propylene glycol circulating through a heat-exchange coil (Figure 68-23). The glycol is heated by the sun's energy in two thirty-tube evacuated solar hot-water collectors located on the roof (Figure 68-24). Whenever the glycol temperature becomes warm enough, a differential

temperature controller automatically activates a circulating pump attached to the tank to circulate the glycol through the heat exchanger. In winter, the hot water is also used to heat the building. No furnace is used for heating. An outside air-to-air heat pump and electric heating coils within the storage tank supplement the solar collectors on very cold days. The operating temperatures are continuously monitored and can be tracked on the BrightBuilt Barn Web site (Figure 68-25).

UNIT 68—SUMMARY

There has been a substantial movement toward sustainable green building design. Both government agencies and private organizations are expending considerable

resources to provide education, establish standards, and certify compliance to ensure a sustainable future. The HVACR industry will be tasked to provide energy-efficient equipment that is installed properly and maintained to guarantee energy savings. While the initial rating systems for green design were most often voluntary, the trend is moving toward an increasing number of mandatory standards and code requirements. You will need to rely on professional journals and regular attendance at continuing education seminars and workshops to keep abreast of the most current regulations.

UNIT 68—REVIEW QUESTIONS

1. According to the Department of Energy, the combined impact of all buildings, both commercial and residential, accounts for more than _____ percent of all electricity usage and _____ percent of all natural gas usage.
2. The DOE's Building Technologies Program has a goal to increase the number of high-performance buildings, which will be _____ percent more efficient than today's typical buildings.
3. What was the first state to develop a mandatory green building standards code?
4. The CALGreen code is established to do what?
5. What makes a building sustainable?
6. From a financial perspective, should owners of a sustainably managed building expect a higher return on investment?
7. Why is it important to meet the building standards during new construction rather than waiting until some later time to incorporate them?
8. What does the acronym LEED stand for?
9. Who developed the LEED rating system?
10. What is a jurisdictional code?
11. What is the IGCC, and what does it serve to accomplish?
12. What are the I-Codes?
13. What is the purpose of the ASTM standards?
14. What is Standard 189.1-2009?
15. What is the National Green Building Standard?
16. What is the ANSI/GBI 01-2010 standard?
17. What are the five main rating system categories for LEED certification?
18. What are the three different tier credentials that can be earned through the LEED program?
19. What are VOCs, and how does it apply to green building programs?
20. How are freezer and cold cases different in a "green" supermarket as compared to a conventional supermarket?

UNIT 69

Indoor Air Quality (IAQ)

OBJECTIVES

After completing this unit, you will be able to:

1. define the meaning of indoor air quality (IAQ).
2. state the HVACR technician's role as it relates to indoor air quality.
3. identify various pollutants and pollutant pathways that affect indoor air quality.
4. list several tools and instruments to help measure and evaluate indoor air quality.
5. explain appropriate strategies to prevent, control, and resolve certain issues related to indoor air quality.
6. set limits that guide when other professionals need to be involved in addressing indoor-air-quality issues.

69.1 INTRODUCTION

A properly trained and certified HVACR technician should be able to communicate how the interacting systems of a building affect indoor air quality with the building owner and the occupants. An HVACR technician who takes the time to expand his knowledge by learning and applying building science will be an extremely valuable resource in the marketplace. These technicians will be far better prepared to positively affect the building environment from an energy and environmental perspective in addition to improving indoor air quality. Providing the occupants with a healthy, safe, comfortable, and sustainable indoor environment often also saves energy and reduces the building's impact on the environment. HVACR technicians have a responsibility to the customer to ensure that the HVACR systems do not negatively affect the indoor air quality or cause other unintended consequences with building systems. Learning the concepts of building science and being able to apply them are parts of an HVACR technician's role in today's marketplace. Properly trained technicians can use their knowledge of building science to provide a building whose systems and occupants are able to work together.

69.2 INDOOR AIR QUALITY DEFINED

Simply defined, indoor air quality (IAQ) is the state of the air contained within an enclosed building. The air may be conditioned or unconditioned, and it may be acceptable or objectionable to the occupants. To achieve acceptable IAQ, the air's temperature, humidity, and velocity may need to be conditioned and pollutants must be removed. Often, when people talk about IAQ they are talking about identifying any source of pollutants or contaminants and taking appropriate actions to remove, control, or prevent their amplification. Amplification in IAQ terms means the contaminant's ability to grow and spread.

"Indoor air quality" has rapidly advanced from a cutting-edge buzzword to an important consideration in building construction and operation. IAQ is now widely acknowledged and accepted as being important in the marketplace.

However, the perception of what constitutes good IAQ and the associated improvements needed to achieve it remain an interesting topic of discussion and debate by those in the industry. For some, improving IAQ has meant simply upgrading air filters or the addition of an advanced air cleaner. For others, it has involved installing humidification or dehumidification systems, coil and drain pan cleanings, or duct cleanings, or even installing heat-recovery ventilation systems. Still to others it means looking at the entire building as a system and looking beyond just the HVACR systems to truly comprehend what is occurring in a building and why it is happening. It involves getting into the science that is affecting the air from a chemical and biological perspective as well as the physics of the air. To truly make a difference and solve IAQ issues properly, a technician needs to understand how a building and its systems interact. HVACR technicians need to understand that the most effective way to address IAQ is by using techniques that eliminate or reduce the source of the pollutants. It will sometimes take multiple strategies working together to fully address complex IAQ issues.

69.3 POLLUTANTS

There are a variety of potentially harmful or damaging pollutants that must be considered when addressing indoor air quality in buildings. These pollutants can affect human occupants and building systems in a variety of ways. There are two major categories of pollutants that must be controlled: chemical and biological pollutants. Within each of these broad categories are many subcategories that an HVACR technician should have a working knowledge of. This is for the safety of both the technician and the occupants. Each pollutant has its own unique characteristics. Where the various pollutants may be encountered in the building varies. There may also be many ways to prevent, control, or resolve issues that might arise from the pollutant being encountered in the indoor environment.

Pollutants can be produced naturally by the earth or may be dependent on some level of human intervention. Radon is a radioactive gas that is produced naturally by the earth. There are also certain elements or compounds

that may mix and interact to produce a potentially harmful contaminant. Some household cleaners can oxidize rapidly and emit a strong, gaseous odor when contacting materials that are commonly found in buildings. Chlorine bleach and ammonia cleaner can react and form chlorine, a poisonous gas. Still other pollutants may result from certain processes taking place. For example, a copier may be producing ozone at a level that it is harmful to the operator and perhaps even coworkers because it is not properly ventilated. Another example is the buildup of carbon dioxide and moisture from the building occupants' breathing. Both water and carbon dioxide can cause IAQ problems in high enough concentrations. Improper operation of a piece of heating equipment can be the source of deadly carbon monoxide from incomplete combustion. Many building materials contain formaldehyde and will produce formaldehyde gas when exposed to higher temperatures and humidity. This pollutant can be harmful even at relatively low levels. These are all examples of situations commonly encountered in the marketplace that an HVACR technician might encounter and have to resolve.

CAUTION

It should be emphasized that this is a basic introduction to the pollutants. It is not intended to be an all-inclusive or exhaustive set of information. What is contained in this unit should help HVACR technicians become familiar with the concepts and to gain a basic understanding of what they might encounter. However, it should not be the only source of information, and it is not intended to instruct technicians how to resolve every IAQ issue they will encounter.

69.4 CHEMICAL POLLUTANTS

Asbestos

Asbestos is a naturally occurring material mined from rocks that occurs in fiber bundles having unusual tensile strength and fire resistance. Asbestos has been banned for use in the United States in certain products since the late 1980s, but it is frequently encountered in older buildings. It can be found in the older buildings in joint compounds, vinyl floor tiles, pipe and boiler insulation, fireproofing, caulks, shingles, and a variety of coatings. Asbestos becomes a potential IAQ problem when it is in a "friable" condition. Friable means that the fibers can easily be released into the air with minimal disturbance. Asbestos also becomes a serious issue when it might be disturbed for any cutting or sanding operations or any demolition. The HVACR technician should not disturb or remove asbestos-containing materials. In many cases, it is best to simply leave material alone that it is believed to be asbestos if it is in good condition and intact. Outside assistance will almost certainly be required if the project requires disturbing asbestos material. Asbestos cannot be positively identified without the services of an outside laboratory to do sampling.

SAFETY TIP

In all cases where asbestos-like material is encountered, the HVACR technician needs to take extra care and caution, as the fibers can cause diseases of the lung, including asbestosis, mesothelioma, and lung cancer. HVACR technicians should never enter a posted area for any reason when working in an environment where asbestos remediation is underway in a part of a building.

SERVICE TIP

When a material suspected of containing asbestos is believed to be the cause of an IAQ problem, the services of another professional should be retained. It is good to have a relationship with a local laboratory and properly qualified asbestos remediation contractor who can address asbestos if it is encountered in the area of operations where an HVACR technician works.

CAUTION

Under most circumstances it is illegal for technicians to remove asbestos from the job site. Asbestos removal must be carried out by licensed asbestos abatement companies. Removing asbestos without the proper equipment can be hazardous to your health and could result in fines for you and your company. If you suspect that an older installation has asbestos, you must request that an approved laboratory test the material to see whether asbestos is present.

Lead

Lead is another pollutant that HVACR technicians will encounter as they work in older buildings. The HVACR technician will need to know how to address lead when it is encountered. While paint that contains lead is often a primary source of airborne contamination, lead can also be found in water and contaminated soils. Lead paint that is in good condition should remain intact. If the paint suspected of containing lead is found to be in poor condition, then it will need to be tested by a laboratory to confirm that it does indeed contain the pollutant, and then it must be properly removed. The paint should not be scraped, sanded, or burnt off by untrained individuals. Lead poisoning can cause damage to many of the body's organs, and lead dust can be easily brought home to spouses and children on clothes. Decontamination is part of the requirement for performing lead remediation work.

CODE TIP

The Environmental Protection Agency (EPA) requires contractors to be certified and follow specific work practices to prevent lead contamination when performing renovation, repair, and painting (RRP) projects that disturb lead-based paint in homes, child-care facilities, and schools built before 1978. Contractors should test for lead paint in dwellings built before 1978 before beginning any remodeling or reconstruction work. If lead is discovered, all contractors who work on the project must be EPA RRP certified and must use Lead Safe Work Practices. Any contractor who neglects to comply could be penalized up to \$37,500 each day.

Radon

Radon is a gas that is produced from radium, which is found in rocks and soil in the ground. A building that is constructed in proximity to a source of this gas can become contaminated easily if the pollutant is not controlled. It should also be noted that radon has been found in water from wells, and this can be a source for the pollutant to enter a building. Radon gas is colorless and odorless. Radon testing should be performed using methods that meet or exceed established industry testing standards. The standard remediation for radon gas is tightening the building envelope and capturing and removing the gases. This is usually done through ventilation. Radon gas that is not addressed and allowed to enter the living space can lead to lung cancer for building occupants.

Combustion

Combustion is a chemical reaction that occurs most commonly inside equipment that is installed in buildings. The byproducts of combustion have the potential to cause significant IAQ issues when they do not vent properly or something causes the combustion process to go wrong. HVACR technicians may need to perform combustion analysis, draft testing, spillage testing, or building depressurization testing when investigating IAQ issues relating to combustion.

CO

Carbon monoxide is a colorless, odorless, and tasteless gas. CO can be produced in substantially harmful quantities when the combustion process becomes incomplete from lack of oxygen or low combustion temperatures. Incomplete combustion and CO may occur from a flame impingement, poor fuel-air mixture, incorrect flame pattern, or combustion air starvation.

Carbon monoxide inhibits the blood's ability to carry oxygen. Extremely low concentrations of CO have been associated with long-term health effects, especially in children, the elderly, and those who have their health compromised by other diseases or ailments. CO levels as low as 9 ppm (parts per million) are deemed as actionable by some credible industry standards. The technician should always exercise extra caution when working in or around

combustion appliances to ensure that the levels do not exceed the OSHA-permissible exposure limits of 50 ppm for an 8-hour time weighted average.

The HVACR technician needs to understand that proper combustion is not only essential to aid them in preventing an opportunity for an IAQ problem to occur, but it is also essential to enable the equipment to operate efficiently, meet manufacturer specifications, and remain clean and serviceable.

SERVICE TIP

The source of CO contamination may not be the appliances but the garage. Cars produce large volumes of CO. CO produced by a car operating in an attached garage can be pulled into the house and distributed by the air conditioner or furnace. This is especially likely if the air-conditioning equipment is located in a mechanical room adjoining the garage.

CO₂

Carbon dioxide is a normally occurring trace gas in the earth's atmosphere. It has been used as one means for measuring IAQ relative to outdoor air quality. When measuring carbon dioxide, the HVACR technician needs to recognize that outdoor air will provide a baseline against which the indoor air can be evaluated. A technician addressing IAQ should recognize when the indoor air concentrations of CO₂ are higher than the outdoor concentrations. Demand-controlled ventilation systems are available that operate when carbon dioxide levels exceed a certain operating setpoint in a building. Keeping inside levels close to the outdoor baseline is the goal. Since CO₂ concentration is addressed by outside air ventilation, it is not possible to reduce the CO₂ level inside any lower than the CO₂ level outside.

NO₂

Nitrogen dioxide is a gas that is poisonous when inhaled. It is a reddish-brown color and has an odor. It can cause serious injury or death even at extremely low levels of exposure, especially to those individuals at risk, such as children, the elderly, and those with respiratory diseases and ailments. Another closely related pollutant is nitric oxide. Together these two pollutants are commonly referred to as NO_x. These are both byproducts of combustion and contribute to acid rain.

Environmental Tobacco Smoke

Environmental tobacco smoke is becoming less of an IAQ problem as more and more authorities having jurisdiction are restricting the use of tobacco products in public places. Where smoking does still occur, it can become an IAQ issue that an HVAC R technician may be asked to address. Since environmental tobacco smoke has an estimated 4,000 compounds in it, it is typically a challenge to address using a single method of remediation. Most often the best solution is a combination filtration and exhaust system.

Mercury

Mercury is a heavy metal. Mercury is also found in the air in particulate form around industrial plants that consume fuels with a high sulfur content. It can be found in buildings in a number of other forms, such as in fluorescent lightbulbs, batteries, thermostats, and thermometers. It is important that HVACR technicians who are addressing IAQ where mercury is found or suspected take special precautions to protect themselves from unnecessary exposure. Mercury must be disposed of properly to avoid cross-contamination.

Volatile Organic Compounds

VOCs are a class of chemical compounds that give off gas due to their high vapor pressure under standard conditions. IAQ is quite often compromised by these compounds, which are found in a number of building materials. They come from paints, carpeting, manufactured woods, and laminates. There are several types of VOCs encountered, include aldehydes, ketones, mercaptans, and hydrocarbons.

- **Aldehydes** Aldehydes are a class of organic chemical compounds. Formaldehyde is the most commonly encountered aldehyde. Varying forms of this chemical are used in pressboard materials like medium-density fiberboard, plywood, particleboard, or oriented strand board (OSB). It is also used in the production of insulation, paints, coatings, glues, and certain fabric materials and is a byproduct produced during combustion, especially from unvented fossil fuel burning appliances.

People are typically exposed to formaldehyde when they breathe air that contains formaldehyde fumes. Formaldehyde can cause burning and watery eyes and irritate nasal cavities and mucous membranes. Other reactions include chest tightness, difficulty breathing, and allergic reactions. The first line of defense against formaldehyde exposure is to use formaldehyde-free products or low-formaldehyde-containing products. Ventilation is a common approach to reducing formaldehyde concentra-

tions when the formaldehyde is coming from products inside the building.

- **Ketones** Ketones are often used in paints and perfumes. The most commonly encountered ketone encountered in IAQ will likely be in paints. When an IAQ issue is raised due to odor from painting, it is often related to the ketones in the paint. Selecting paint products that are low in VOCs will typically lower the amounts of ketones.
- **Mercaptans** Mercaptans are often used as an odorant in natural gas for safety, since the gas is odorless. Those who are chemically sensitive can react to even trace amounts in the parts-per-billion range of these odorants. It does not take a large dose to affect IAQ for these people. Mercaptans can enter the building through gas leaks and combustion products entering the building. To reduce mercaptan levels, eliminate any unvented combustion appliances and make sure the vents on vented appliances are operating correctly.
- **Hydrocarbons** Hydrocarbons are substances that contain only the elements hydrogen and carbon. They are often used as fuels. Many of our rubber products, asphalts, plastics, and fiber materials contain hydrocarbons in aromatic form. These hydrocarbons can cause IAQ issues in buildings.

Particulates

Particulates can arise from natural processes such as wind erosion, sea spray evaporation, volcanic eruption, and biological processes. However, natural sources usually create far less contamination than manmade activities. Some of the manmade activities that cause air contamination are power plant operation, industrial processing, various types of transportation, and agricultural activities.

A micron is a millionth of a meter, or one thousandth of a millimeter. Figure 69-1 shows the relative size of some particulates in microns. By comparison, human hairs range

Figure 69-1 Sizes and characteristics of airborne solids and liquids.

in size from 25 to 300 microns. Particles smaller than 10 microns are not visible to the naked eye. Smaller particles, such as smoke, are visible only in high concentrations. Health authorities are concerned with particles that are 2 microns or less because they can be retained in the lungs. Note the size range of a few common pollutants: pollen, 10–100 microns; bacteria, 0.4–5.0 microns; tobacco smoke is a solid ranging in size from 0.1 to 0.3 microns; and viruses, 0.003–0.06 microns.

Pesticides

Pesticides as well as insecticides, rodenticides, herbicides, and fungicides are chemicals used for controlling certain plants, animals, and parasitic organisms. They are designed to kill plants and animals and can be extremely harmful or even fatal to humans. They are important to the technician addressing IAQ because the compounds can be carried in on the feet of occupants of the building and become airborne, causing reactions in some individuals. These items may be in high enough concentration on surfaces of or around a building that they can actually be drawn in by natural infiltration entering the building through the cracks and crevices.

Ozone

Ozone (O₃) is an oxidizing agent with a very pungent odor. It is harmful to humans and animals and will cause severe irritation of the mucous membranes in the airway. Ozone is produced by electrical discharge and certain types of ultraviolet radiation. Ozone is an excellent agent for breaking down certain hydrocarbon substances as well as deodorizing air and purifying water, but it must be used carefully. The levels of ozone present in a space must be checked throughout the process of sanitizing with proper testing equipment because ozone can cause damage to or harm items it comes into contact with through rapid oxidation. Ozone should never be introduced into occupied living spaces, as it will cause harm to humans and animals.

69.5 BIOLOGICAL POLLUTANTS

Pests

Pests have the potential to introduce biological contaminants into an indoor air environment. In the case of bats and mice, their fecal matter can be hazardous to humans. These droppings are often encountered when entering areas of buildings like ceilings, soffits, or attics. The droppings need to be carefully dealt with. The fecal material should not be inhaled or allowed to be dispersed, as it could cause new or additional IAQ issues. Care should also be taken when performing pressure diagnostics on buildings using fan-assisted pressurization devices. Creating a large negative pressure in the building can pull these contaminants into occupied space. Mice can carry foodborne bacteria such as salmonella, and deer mice in some parts of the country carry the hantavirus. The disease can spread when a person breathes in air or comes into contact with contaminated surfaces exposed to the saliva, urine, or feces from an infected mouse. From an IAQ perspective, one of the best ways to prevent infection in a building is to keep the

building tight and not let anything in. If there is evidence of infestation from pests, then this needs to be properly addressed by trained professionals.

Bacteria

Bacteria are common in the indoor and outdoor environment and can be the cause of diseases in plants, humans, and animals. All bacteria are not harmful. For example, bacteria are used in pickling and fermenting processes. Bacteria are classified by their shape primarily as well as their need for oxygen and whether they are affected by heat. The quantity of bacteria growing is largely impacted by the host it is living on or in as well as temperature, air movement, light, and moisture. Bacteria may grow in soil, water, food, and in humans and animals, to name a few potential hosts. Bacteria may often be found as a result of a water or moisture problem. These bacteria tend to live off of dead organic matter and will thrive in many of the materials commonly found in and around our buildings.

Fungi

Fungi are organisms that absorb their food from an external source. This group includes molds, mildew, yeasts, and mushrooms. An HVACR technician will have numerous encounters with items that fall into this category. Fungi generally thrive on organic materials, although there are some that require a living host organism and are parasitic in nature. Much like bacteria, there are fungi that are good and bad. Fungi can cause disease in humans. From an IAQ perspective, it is often the airborne mold spores containing mycotoxins that need to be addressed.

It is important to recognize that most of these items occur everywhere. However, an HVACR technician should learn to recognize that the presence of fungi may be an indication of other problems. For example, *Stachybotrys chartarum* is a mold that thrives in materials containing cellulose that have been water damaged. If it is found, then there is a need to investigate where the water is coming from. The likelihood of finding water damage along with the source of the contaminant is extremely high.

Viruses

Viruses invade the human immune system and cause diseases. They produce toxins and are smaller than bacteria. Viruses are often very difficult to destroy. They are not something that an HVACR technician will normally be able to address. It should be noted, however, for future reference that there is ongoing research being performed that looks at how HVAC and IAQ equipment may be used to help in the control of certain viruses, particularly in highly controlled laboratory settings. High concentrations of ultraviolet light have been shown to be effective in killing viruses in the air.

69.6 POLLUTANT PATHWAYS

In addition to understanding the pollutants that might be encountered, an HVACR technician needs to understand the pathways that allow the pollutants to enter and spread. The possible pollutant pathways through the building envelope or mechanical systems are extensive.

Figure 69-2 Leaks in return ductwork located in a crawlspace can pull in contaminants from the crawlspace.

Outside to Inside

One of the more common pollutant paths occurs from outside the building to inside the building. For example, window or door openings, plumbing stacks, and chimney chases are obvious examples. Some common pathways would include a duct system (Figure 69-2), wall chase (Figure 69-3), plumbing chase (Figure 69-4), chimney stack (Figure 69-5), or an electrical penetration (Figure 69-6).

CAUTION

It is imperative when looking to resolve IAQ problems that one identify the pollutant pathways to determine if there is any cause-and-effect relationship between them. Failure to identify these pathways may result in providing a solution that is ineffective or causes other unintended consequences.

Figure 69-3 Panned floor joists can suck air from both the crawlspace and the attic.

Figure 69-4 Leaks around plumbing can provide a path for pollutants.

There are also less obvious examples, such as the space between the sill plate and foundation (Figure 69-7), foundation wall cracks (Figure 69-8), and voids in air barriers, vapor barriers, and thermal materials (Figure 69-9), attic hatches (Figure 69-10), and top plates (Figure 69-11). There are also substantial pathways through vent pipes and exhausts, fresh air intakes, and other openings made for mechanical devices such as attic fans. These can be pathways under some conditions but not under other conditions. Each of these is an

Figure 69-5 Pollutants can be pulled in through a chimney.

Figure 69-6 The holes in framing for wires can provide a pathway for pollutants.

Figure 69-9 Gaps in crawlspace vapor barriers can increase the pollutants inside the crawlspace.

Figure 69-7 The crack between the sill and the foundation can allow infiltration to carry pollutants inside.

Figure 69-10 Air gaps around attic hatches can provide a way for infiltration to carry pollutants into the house from the attic.

Figure 69-8 Cracks in the foundation wall can provide a pathway for pollutants to enter.

Figure 69-11 The outer wall top plate is exposed to unconditioned air; cracks and penetrations in the top plate can create a path for infiltration and pollutants.

Figure 69-12 The holes in the framing above this power panel create a conduit for air and pollutants from one part of the house to the other.

outdoor-to-indoor connection. HVACR technicians often look first at the mechanical system as the source for IAQ problems since they do not typically focus much attention on the integrity of the building envelope. Technicians should know where and how to identify issues in the building envelope. They should also be able to measure the amount of building leakage to the outside and understand how this interacts with the building mechanical systems. Understanding how a building's construction and its systems interact is called building science.

One Location to Another Inside the Building

Another common pollutant path is from one location inside the building to another location inside the building. Walls, floors, ceiling cavities, soffits, chases, and ductwork are all typical paths. Holes through framing can create an unintended pathway between adjacent areas of a building (Figure 69-12). One common situation that an HVACR technician is often asked to address is carbon monoxide presence in a building. It is important that an HVACR technician understand the sources of CO because some may be more effectively controlled at the source, while other sources, such as an attached garage, may require addressing the pressure boundary between the garage and the occupied space. Still other situations, like CO generated from a kitchen area where cooking appliances are located, may require some spot ventilation. Each of these situations might be encountered by technicians. Knowing how to address the suspected problems is important.

Benefits of Locating and Sealing Pollutant Pathways

Another reason that a technician needs to address pollutant pathways has to do with energy effects. This is an IAQ issue because as energy costs increase, HVACR systems may be operated less or at the extremes of the typical comfort ranges to try to save money. This might involve higher or

lower temperatures and more substantial variations in relative humidity levels; and outdoor air ventilation rates may also be affected. A building that has high rates of infiltration will add additional load to the HVAC systems. This may cause new or replacement systems to be sized larger than is truly needed. Oversized systems also use more materials, which increases the building's impact on the environment. The same pathways that can let in pollutants are also a major area for energy waste. Defects in the building envelope affect HVAC system performance, energy use, and the IAQ of the building.

69.7 BUILDING SYSTEMS

The air pressure inside a building can be about the same, lower than, or higher than the air pressure outside the building. Residential buildings seldom seek to control the pressure inside the building, but commercial structures typically try to maintain a positive pressure. A building with a negative pressure will experience infiltration (air leaking in) through all the cracks and holes between the outside and inside. Drafts by windows and doors in the winter are a good example of infiltration. Buildings with a positive pressure will experience exfiltration (air leaking out) through all the cracks and holes in the building. Outside air must be introduced into the building to maintain a positive building pressure.

Ventilation Versus Infiltration

Infiltration is air that leaks in on its own because the pressure in the building is lower than the pressure outside. Infiltration provides a path for pollutants to enter the building. Ventilation air is intentionally brought in to maintain a positive building pressure and to provide air for vent fans and draft hoods. Air introduced through ventilation can be controlled, filtered, and conditioned before being introduced into the building. Diagnostic testing can help quantify the amount of air infiltration/exfiltration and locate the pathways it is capable of taking. These pathways can be critical pieces of information when evaluating the IAQ in a building. A building's air change information will also have an important impact on load calculations and may affect the size of the heating or cooling equipment.

69.8 TOOLS AND INSTRUMENTS

There are many tools and instruments that can be used by a technician when addressing IAQ in a building. Each of these tools and instruments will require that technicians take the time to learn how to use and master them. A technician learning how to use these tools and instruments should plan to work with another technician who has extensive experience using the devices to ensure that they are being used and understood correctly. Failure to use the tools and instruments properly might lead a technician to make decisions that could expose the occupants to unnecessary risks, jeopardize their own safety, and increase the liability exposure of their employer should their actions be determined to be the cause of death, injury, or destruction.

Renovation, Redecorating, Remodeling <ul style="list-style-type: none"> • Discuss IAQ concerns with architects, engineers, contractors, and other professionals. • Obtain MSDSs; use materials and procedures that minimize IAQ problems. • Schedule work to minimize IAQ problems. • Arrange ventilation to isolate work areas. • Use installation procedures that minimize emissions from new furnishings. Smoking <ul style="list-style-type: none"> • Eliminate smoking in the building. • If smoking areas are designated, provide adequate ventilation and maintain under negative pressure. • Work with occupants to develop appropriate non-smoking policies, including implementation of smoking cessation programs.
--	--	---

Figure 69-13 Example of an IAQ checklist.

Checklists

Checklists ensure that critical steps in a process are not missed (Figure 69-13). Establishing and using methodical procedures will improve accuracy and consistency. This will also ensure that a technician has all information needed to make a proper recommendation or convey correct information to others who will rely on it. These checklists can be organized into a book format or used individually for various test procedures, evaluation procedures, and even common daily routines.

Surveys

Surveys are an essential instrument for every technician to have and use when addressing IAQ issues. They will guide the technician through a series of questions that should be asked before, during, and after the assessment is performed. This process will systematically allow the technician to identify building areas for IAQ improvement and to understand the wants and needs of the occupants.

Figure 69-14 This handheld IAQ meter can monitor VOCs, CO₂, CO, %RH, and °C/°F in one place. (Courtesy of Gray Wolf Sensing Solutions)

Detectors

Detectors may be used for identifying a variety of substances, such as gases, refrigerants, and other indoor air contaminants such as volatile organic compounds (Figure 69-14). Detectors are typically not capable of quantifying the amount of a pollutant found; they will only indicate that it is present. Where quantifiable data are needed, such as in CO levels, a monitor or instrument with an ability to chart, record, or in some way quantify the amount of pollutant being collected is necessary (Figure 69-15).

Fan-Assisted Pressurization Devices

Blower doors and duct blasters are excellent tools that an HVACR technician can use for the purposes of identifying

Figure 69-15 Carbon monoxide detector. (Courtesy Testo, Inc.)

Figure 69-16 Blower doors are used for pressurizing entire buildings for testing. (Courtesy of the Energy Conservatory)

and quantifying the air leakage rates, locations in buildings, and duct systems. These tools allow measurement of leakage rates. Blower doors are used to pressurize an entire building (Figure 69-16). Duct blasters are used to pressurize just the duct system (Figure 69-17). The information gained from this diagnostic testing will serve to provide accurate input into load calculations being performed related to infiltration. An IAQ investigation may reveal pressure differences from one part of a building to another, which would cause pollutants to flow through pathways that were not detectable without instruments. In ducted systems, the identification of the leak points and amount of air leakage can be very useful in determining why heating or cooling is not working as expected.

Manometers

Manometers should be a familiar tool to an HVACR technician. These devices are used in measuring the pressure of liquids and gases in relation to atmospheric pressure. There are a number of different types of manometers used for the work of an HVACR professional. Common manometer types include the U-tube manometer, commonly used in measuring gas pressure, and the inclined manometer, used in measuring static pressure and velocity pressure in ductwork. Digital manometers are commonly used for IAQ work (Figure 69-18).

Figure 69-17 Duct blasters are used for pressurizing the duct system for testing. (Courtesy of the Energy Conservatory)

Figure 69-18 Digital manometers are frequently used in IAQ work. (Courtesy of Gray Wolf Sensing Solutions)

Depending on the instrument and its precision, these devices may enable accurate measurement of pressure down to 1 Pa or .004 in wc. This is important when evaluating the small pressure differences between different parts of a building or draft pressures where relatively small variations in pressure can mean the difference between something working properly and something having serious problems.

Figure 69-19 Infrared cameras can help spot areas that have thermal leakage. (Reproduced with permission of FLIR Systems)

Infrared Cameras and Thermal Imagers

Infrared cameras are a tool that can provide the HVACR technician addressing IAQ with a visual picture to determine what is happening inside or outside of a building (Figure 69-19). Thermal imagers are an excellent tool for use in explaining to owners and occupants of a building why something is or is not happening. The best feature of an IR camera is that it gives the technician the ability to provide a graphic record of the before and after conditions.

Particle Counters

There are now handheld instruments available that can count the number of fine particles in the air. These handheld instruments can count the concentration of particles in the air down to 0.3 microns. Uses include testing air filtration, verifying clean room particle concentration, and investigating IAQ. While these instruments are still relatively expensive, they are far less expensive than just a few years ago.

Sampling Kits and Devices

Sampling kits are available for capturing various pollutants through bulk sampling, surface swabbing, and airborne capture. There are a number of kits readily available that can be used simply for providing guidance on next steps. However, these kits are often not too accurate and may provide no quantifiable data as to the contaminants' ability to cause harm. In most cases, precision is needed for decision making and in fact preferred for liability reasons. The services of an outside professional should always be considered who will have the proper instrumentation and sampling techniques needed as well as laboratory support. An example where testing needs to be precise is evaluating suspected mold, lead, asbestos, and volatile organic compounds.

69.9 PREVENTION, CONTROL, AND REMEDIATION STRATEGIES

There are many different strategies available for preventing, controlling, and eliminating IAQ issues. The three most common strategies for reducing indoor pollutants are eliminating the source of the pollutants, ventilating to dilute the pollutants and reduce their effect, and using filters and cleaners to remove the pollutants from the air. Another strategy that will be discussed is called prevention through education.

Source Control

Source control may also be described as elimination of the pollutant. It is the best choice when it comes to managing IAQ. Source control typically involves the physical removal of a known or suspected pollutant from the building. For example, removal of mold-contaminated materials would be a form of source control. Another example of source control would be removing an element contributing to the problem—for example, for mold to flourish it needs a moisture source; if we remove the source of moisture, then we can remove the ability for mold to grow.

Substitution

Substitution is a variation of source control that is best described as care in product selection. This strategy is becoming increasingly important not only for IAQ purposes but also as the push for a greener planet becomes the focus of so many. Green products are typically evaluated based on their use of recycled content, reusability, renewability, embodied energy, durability, and overall impact on the environment. It is this last attribute about overall impact on the environment that is the most important for IAQ. The HVACR technician who is addressing IAQ can rely on the strategy of substitution to find the right product or material that can be used to improve or prevent an IAQ issue from occurring. Some good examples of alternative products that might be selected include alternative duct lining and insulating products that do not negatively impact IAQ. Duct sealing and other sealants that are low in or contain no VOCs might be another product decision that an HVACR technician addressing indoor quality can rely upon. One of the keys to IAQ-friendly product selection might lie in a careful review of the product's material safety data sheet (MSDS). An MSDS contains a wealth of information on the material and its properties that can guide HVACR technicians in understanding if they are contributing to an IAQ issue.

Isolation

Isolation is also a variation of source control. Isolation may also be described as separation or encapsulation of the pollutant or contaminant. This strategy does not remove the pollutant or contaminant from the building but will serve to keep it from entering the occupied spaces. Isolation may involve installing an encapsulating-type product over the top of an existing product, or it may involve the sealing of one building space from another to eliminate the

pollutant pathways. Oftentimes the latter strategy is coupled with some other strategy, such as dilution, to reduce the potential for harm when someone enters the isolated space. A good use of the encapsulating strategy might when encountering existing asbestos-covered pipe that has been tested and is not considered friable. While airborne asbestos fibers would become harmful if the material is disturbed, simply encapsulating with another product may be a viable option to prevent that from occurring and allow it to be left in place without the need to be concerned about its presence. This would be an example of isolation without removal.

Another strategy would be where a particular commercial process is taking place—for example, a printing and copying room in an office facility. The process is not something that can be stopped, as it is critical to a successful businesses operation. In this example, it would be necessary for the room where the process is taking place to be isolated from another room, and then for the safety of the users there would need to be a system of supply and exhaust ventilation. We cover this concept in the next section.

Dilution

Dilution may also be described as a reduction strategy, as it involves a form of exhaust or ventilation but may not completely remove the contaminant. This strategy may involve bringing in air from outside to dilute the harmful pollutant or contaminant being generated in that space and exhausting air from the space to reduce the impact of the pollutant or contaminant. Care needs to be taken when using dilution to ensure that the space remains properly balanced in terms of its pressure relationship with other rooms in the building. Care also needs to be taken to ensure that vents on furnaces, water heaters, and fireplaces work properly. Bringing in more air than is capable of being exhausted can force the pollutants into other connected spaces. Exhausting more air than is being brought in can draw other contaminants in from adjoining connected spaces. To keep the pressure in an area of the building the same, as much air must be brought in as is exhausted out (Figure 69-20). Air that is brought in to allow proper ventilation is called makeup air. Using an energy-recovery ventilation system is one way to maintain a proper balance between makeup air and exhaust air without losing large amounts of heating or cooling in the exhaust air (Figure 69-21).

Figure 69-20 It is necessary to provide makeup air from outside for ventilation to work properly.

Figure 69-21 An energy-recovery ventilation system can reduce the energy cost of ventilation.

Filtration

Filtration is a reduction strategy and involves air cleaning that typically involves moving air across a surface that is made of various types of filter media material. Filtration is covered in a separate unit and will not be discussed in detail in this section. Care should be exercised to ensure that fan curves and motor capabilities are not exceeded when advanced filtration systems are used on the equipment. In some cases, the attempt to filter pollutants may actually be negatively affected by the installation of advanced filters. This can also cause other problems, such as premature motor failures and excessive use of energy. If filters are not replaced or cleaned regularly, the filter itself can become a pollutant source (Figure 69-22).

Prevention by Education

This is a strategy that is instrumental in achieving long-term and sustainable goals of an IAQ program. It should be coupled with any number of the existing strategies.

Figure 69-22 This filter has collected enough dust that it is now a source of pollutants.

When properly executed, this strategy involves the building owner, occupants, and mechanical systems contractor to address activities that affect the building's indoor air environment. For example, maintenance staff may receive training on cleaning drain pans and condensate lines as well as on the use of chemical-free cleaning methods. Occupants might receive training on the use of equipment or disposal of certain products or waste materials that can cause potential IAQ issues, such as lightbulbs containing mercury, cooking exhaust fans, or bathroom ventilation, to reduce potential moisture problems. The owners of buildings might receive training on systems that can reduce their risk for an IAQ problem becoming a crisis. For example, the owner might be trained on how combustion appliances that are not functioning properly can cause the potential for a CO problem or why oversizing air-conditioning equipment can lead to moisture problems. The key is to condition the behavior of the individuals to prevent problems instead of waiting until the problems have occurred.

69.10 KNOWING YOUR LIMITS

There are likely to be certain aspects of IAQ that are going to be beyond the HVACR technician's capabilities without additional specialized training and professional credentialing. That is not to say that the individual cannot pursue the opportunity and achieve the requirements. However, HVACR technicians need to be careful that in the course of their work they do not overstep their own limits, violate laws and regulations, and, most important, jeopardize life, limb, or property through actions that cause death, injury, or destruction. Clear boundaries need to be established by an HVACR technician addressing IAQ that will ensure that the most appropriate action is taken when a certain situation is encountered. For example, when asbestos, lead, radon, or mold is suspected, the HVACR technician needs to do certain things differently to address the issue than perhaps if a combustion safety problem were encountered. It is far too easy for a human being to get caught up in the moment when attempting to resolve an issue and to overstep one's abilities. Having clear, preestablished limits as well as systems of checks and balances will make it much easier for HVACR technicians to perform their jobs in an organized and methodical manner. It is also valuable for an HVACR technician to set up checklists to guide actions to be taken. This is true for any work being done, not just that related to IAQ. Checklists are a tool used to protect the interests of both the customer and the technician. The customer is going to be much more comfortable knowing that a methodical system has been followed instead of someone simply winging it. It is also a well-known fact that our airline industry uses checklists to ensure that critical steps are not missed in the process of flying airplanes. While we recognize this is not a foolproof method, it helps to manage risk, as you do not get a second chance when you are in the air and mistakes are made. An HVACR technician who is addressing IAQ should give serious consideration to using this approach.

69.11 SAFETY IN IAQ

While this unit is not specifically focused on safety, safety is paramount in all that we do. It is imperative that we do not forget the relevance of being safe when it comes to IAQ work that an HVACR technician may become involved in. There are countless potential hazards that might be encountered, including water hazards, confined spaces, poisoning from ingestion or exposure to harmful or potentially toxic chemicals or biological contaminants, climbing on ladders or scaffolds or surfaces where slips and falls might occur and working in and around systems that might cause electrical, fire, or explosion hazards. Always use personal protection items such as hard hats, gloves, eye protection, hearing protection, protective suits, boots, respirators, and fall protection. Safety procedures should also be practiced, including lockout, tag-out, confined-space safety practices, electrical safety, and fire safety. The importance of safety in and around the job site should never be secondary. An HVACR technician is a first line of defense in the safety effort, and all work must be performed safely at all times. Your life and that of others will depend on it.

69.12 MAKING IAQ HAPPEN

To make IAQ happen, the technician needs to understand what the customer wants and provide solutions that address the customer's concerns. The technician needs to provide guidance because the customer will be relying on the expertise of the HVACR technician to recommend appropriate strategies. If the customer does not know what it takes to make something work right and the technician does not tell them, then IAQ will not happen. It is better to discuss IAQ strategies before there is a problem. The cost of remediation and control after a problem has occurred is usually higher than taking preventative measures ahead of time. So the best course of action when it comes to IAQ is to make it happen right, the first time.

UNIT 69—SUMMARY

After completing this unit, the HVACR technician should be able to define the meaning of IAQ; state the HVACR technician's role as it relates to IAQ; identify various pollutants and pollutant pathways that affect IAQ; list several tools and instruments to help measure and evaluate IAQ; explain appropriate strategies to prevent, control, and resolve certain IAQ issues; and to set limits that guide when other professionals need to be involved in addressing IAQ issues. The HVACR technician who begins to understand and articulate these concepts will be well on the way to becoming a valuable asset to consumers and contractors in the marketplace.

WORK ORDERS

Service Ticket 6901

Customer Complaint: Visible Airborne Contaminant
Equipment Type: Commercial Building with Drop Ceiling Return

An HVACR technician is brought in to address an IAQ problem where the air conditioning is suspected of spreading an airborne contaminant, most likely pollen, throughout the building. The technician encounters some slightly open windows in an office and recognizes that allergens like pollen from some nearby flowers and trees is being allowed to get inside an office space, triggering the suspected IAQ problems for a number of sensitive occupants. The technician decides to close the windows and instructs the occupants to use the air conditioning, believing the problem would simply go away.

Unfortunately, the problem proceeded to get worse and become more widespread after this action was taken. The allergens already in the building were further spread through the building by the air-conditioning ductwork. This caused even more of the sensitive occupants in other parts of the building to have allergic reactions. In addition, the presence of the contaminants seemed to increase exponentially, which was puzzling. The technician decided to recommend using some advanced air-cleaning devices inside the building and in the mechanical system as a solution to the problem. The devices indeed lowered the impact of the allergens spreading throughout the system, but this approach failed to address the source of the problem, which is still unidentified.

In this case, the pollutant pathway that is allowing the contaminant to enter the building is from outside. The technician has failed to understand that pollutants enter a building through not only mechanical systems but also the building envelope and that these two interact. In this situation, the technician should have taken the time to determine where the pollutant was coming in from, not to simply assume it was from open windows or from contaminants already inside the building. It was actually being caused by pressure imbalances in the building space. This was allowing the allergen to be conveyed throughout not only in the ductwork but also a number of open building cavities, including the open return-air plenum above the dropped ceiling, which was in fact drawing air in from outside through the building envelope. The proper solution to this problem would have been to air-seal the outdoors from the indoors to prevent the contaminant from being drawn in and ideally ducting and sealing the return-air system to eliminate the chance for this to happen. Filtering this air certainly helped reduce the impact of the problem, but it did not fix the problem because it was more complicated and the technician did not understand this interaction.

Service Ticket 6902**Customer Complaint: CO Alarm Going Off****Equipment Type: Residence with Attached Garage and Mechanical Room off of Garage**

A customer complains that his CO alarm sounds occasionally, and he has called a technician to check the combustion of the furnace and water heater. The technician finds that the furnace and water heater are both operating correctly and that their vents are operating properly. The technician notices that the combustion air grille in the door leads to the garage and asks the customer when the alarm sounds most often. The customer says that the alarm goes off typically after he has left for work in the morning, annoying his wife. The technician asks the customer if he runs his car in the garage. The customer says that he warms his car up in the mornings with the garage door open. The technician shows the customer the CO level in the garage with the car operating and the door up to demonstrate the high levels of CO that build up even with the door open. The technician suggests that the CO is coming from the car, traveling into the mechanical room through the combustion air grille, and entering the ducts through small leaks in the ductwork and furnace cabinet. The technician recommends moving the combustion air grille to an outside wall, replacing the door with a tight-sealing door, and sealing the ductwork to prevent leakage into the return ducts. However, the primary recommendation is to quit operating the car while parked in the garage.

Service Ticket 6903**Customer Complaint: Musty Smell from Air Conditioner****Equipment Type: Split-System Air Conditioner with Blower and Coil in Crawl Space and a Filter Grille in the Hall**

A customer complains that the air leaving her vents stinks with a musty odor. The customer says she purchased a high-efficiency panel filter at the local home improvement warehouse and installed it in the filter grille in the house but that it has not helped solve the problem. The technician finds that the dirt in the crawlspace is not covered by a vapor barrier and that the floor joist space is used as a chase for the return air. The technician explains that the seal between the floor joists and the sheet metal is not airtight, so the return air is constantly sucking in crawlspace air. Since the dirt in the crawlspace is

exposed, dirt, mildew, and mold spores are also drawn into the system. To stop the entry of contaminants, the technician recommends covering the crawlspace with a vapor barrier and replacing the panned returns with ducted and sealed returns. The technician recommends a duct cleaning to help remove the contaminants already introduced into the system. Finally, the technician recommends removing the filter in the filter grille and installing a high-efficiency air cleaner at the unit, explaining that the high-efficiency 1-in filter made the problem worse by creating a lower pressure in the return ducts due to the pressure drop across the filter.

UNIT 69—REVIEW QUESTIONS

1. Define IAQ.
2. What needs to be addressed to achieve acceptable IAQ?
3. What is amplification?
4. Explain the technician's role in IAQ.
5. Name five pollutants that would be categorized as chemical in nature.
6. Name three pollutant areas that would be categorized as biological in nature.
7. What odorant is commonly used in natural gas?
8. What are the two most common pollutant pathways?
9. What is the best method to use for controlling IAQ?
10. What are other methods used for controlling IAQ?
11. What tool or instrument can be used for ensuring that critical steps are not missed in a test procedure?
12. What tool or instrument can be used for ensuring that critical steps are not missed when interviewing occupants?
13. State the primary difference between a detector and a meter.
14. What tool or instrument can be used for measuring infiltration or exfiltration in a building?
15. What tool or instrument can be used for measuring leakage in ductwork?
16. Why is environmental tobacco smoke difficult to remove from the air?
17. Explain why safety is so important when addressing IAQ.
18. Name some pollutants that require lab testing for positive identification.
19. What is the viral disease that certain mice can carry?
20. Why is it necessary for an HVACR technician to understand the building systems?

UNIT 70

Residential Load Calculations

OBJECTIVES

After completing this unit, you will be able to:

1. discuss the importance of a heat load calculation.
2. explain the difference between heat loss, sensible heat gain, and latent heat gain.
3. construct a U factor for a building panel given the R values of the components.
4. construct an HTM given a U factor and a design temperature difference.
5. discuss the effect that daily temperature swings have on heat gain.
6. explain the difference that house orientation has on solar heat gain.

70.1 INTRODUCTION

Heating and air-conditioning equipment provides the most comfort at the least cost when it is properly sized. The calculations done to determine the amount of heating and cooling required for a particular building are called heat load calculations or a heat load study. In the winter, a load calculation is done to determine how fast the building loses heat. In the summer, the load calculation is done to determine how fast the building gains heat. The calculations determine the size of the equipment that will be used to condition the building. The load calculation is the first step in choosing the equipment and sizing the ductwork. The purpose of this unit is to raise the student's awareness of the factors involved in performing accurate heat load calculations; it is not intended as a complete calculation procedure.

70.2 WHY LOAD CALCULATIONS ARE NECESSARY

Heat load calculations are necessary to properly match the equipment capacity to the building requirement. The two primary reasons for doing a heat load study are to properly size the heating and cooling equipment and to design the duct system to deliver the correct amount of air to each room or zone. A shell load is a calculation treating the entire house like one big room. This is fine for sizing the equipment, but is no help for sizing the ductwork. A room-by-room study is necessary to properly size the duct system because the duct design is based on the required heating and cooling load for each room or zone.

There are many variables to take into account when performing load calculations. The sheer number of factors to consider and the amount of number crunching involved can discourage contractors from performing accurate load calculations. One of the most common quick-and-dirty methods involves dividing the building's square footage by a factor to arrive at an equipment size. There are two obvious problems with this method: all buildings are not the same, and all rooms within a single building are not the same. The time spent doing a careful survey of the building

and performing accurate load calculations will save time and money. It is time-consuming and expensive to attempt to make an incorrectly sized and applied system work. This unit concentrates on residential applications.

70.3 LOAD CALCULATION METHODS

Residential and commercial load calculations have unique characteristics that are best served by using a procedure especially designed for each specific system type. A few of the differences between residential and commercial load calculations are as follows:

- **Ventilation** Commercial buildings typically have much higher ventilation rates.
- **Lights** The heat gain from lights in most commercial buildings is a major heat load.
- **People** The people in many commercial buildings are a major source of heat gain.
- **Machinery** The heat from equipment and machinery is often a major source of heat gain in commercial buildings.

The Air Conditioning Contractors of America (ACCA) has developed load calculation procedures that help organize the required information and simplify the process of performing an accurate load calculation. Current manuals include Manual J, 8th edition, and Manual J, 8th edition, Abridged, for residential calculations. Manual N, 5th edition, applies to commercial calculations. These calculation procedures provide tables with factors and data necessary to produce a handwritten spreadsheet. Many computer-based solutions are now available to automate the process.

Manual J, 8th edition, provides tables and procedures for two types of load calculations: peak load procedure and average load procedure. The peak load procedure determines the peak load for each room or zone. Loads are calculated for each room or zone at the time of day in mid-summer that represents the highest load for that exposure. Peak load procedure can be used for zoned systems or for rooms with large exposures of glass. The average load procedure simplifies the calculations by averaging the factors over

different times of the day to arrive at a single factor for each exposure, regardless of the time of day. The majority of residential load calculations can be done using the average load procedure. Manual J, 8th edition, Abridged, only includes the average load procedure. The abridged edition also only has data on common forms of residential construction.

TECH TIP

There are many computer programs available that automate load calculation procedure. However, it is still necessary to collect all the relevant data from the plans or a building survey. The programs primarily save you the time required to look up factors in the tables and do the calculations. Probably the biggest advantage of computer-aided load design is the ability to make changes and quickly see their effect. A customer might be better off spending more money on sealing and insulation than on purchasing a larger unit. This can be easily demonstrated using computer-aided design.

70.4 RESIDENTIAL HEAT-LOSS FACTORS

Heat loss occurs in the heating season when the building is warmer than the outside. Figure 70-1 illustrates common types of heat losses. The primary types of heat loss in a residential building are the following:

- Transmission losses
- Infiltration losses

- Ventilation losses
- Duct losses

Transmission Losses

Transmission losses occur because of a temperature difference between the inside and outside. Heat is transmitted through walls, windows, doors, floors, and ceilings from the inside to the outside.

The heat loss through these surfaces varies with each of the following factors:

- The type of material
- The thickness and thermal conductivity of the material
- The area that is exposed to different temperatures
- The temperature difference between the inside and the outside

Infiltration Losses

Infiltration is air that leaks into the house through cracks and openings. Infiltration can be a significant heat loss because the warm, conditioned air is replaced with cold air from outside. The most obvious places where infiltration occurs are windows and doors. However, infiltration also occurs in walls between the sill and the foundation and in other openings, such as fireplaces.

Ventilation Losses

Ventilation air is air that is brought in on purpose. Like infiltration, ventilation is a heat loss because warm, conditioned air is replaced with cold, outdoor air. However, a big advantage of ventilation is that it can be controlled.

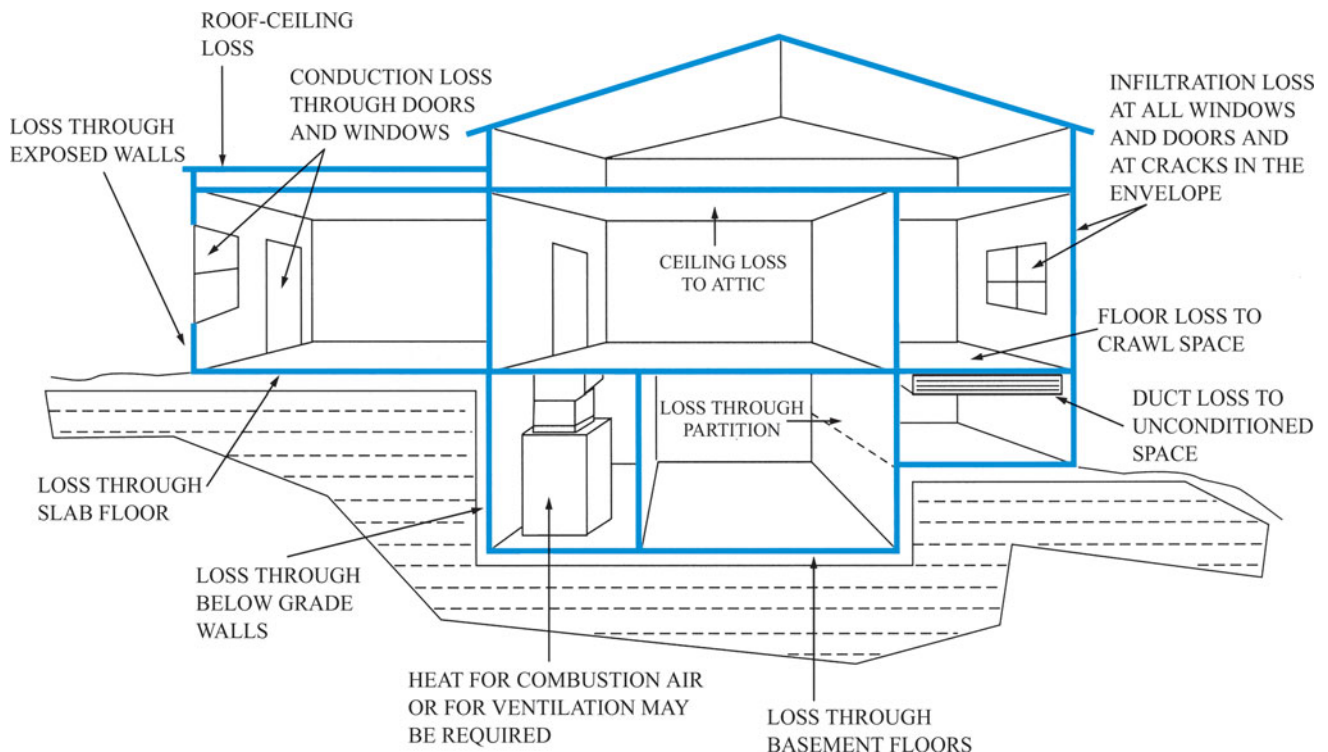

Figure 70-1 Winter heating loads. (Courtesy of Air Conditioning Contractors of America (ACCA). Copyright ACCA.)

Ventilation air can be filtered, and the amount entering can be controlled. Also, ventilation losses can be reduced by using an energy-recovery ventilator. Ventilation losses are significant in commercial structures but play only a minor role in most residential buildings.

Duct Losses

There are really two types of duct losses: leaks and transmission losses through ducts located outside the conditioned area of the building. Duct leaks add to the overall infiltration in the building. The infiltration due to duct leaks can easily exceed the infiltration in the rest of the building. This can be addressed through proper duct installation. Duct transmission losses occur when the duct is located in an area exposed to outdoor temperatures, such as an attic or crawlspace. These can be reduced by insulating the duct, but they cannot be eliminated. The only ways to totally eliminate duct losses is to locate the duct inside the conditioned space or use ductless systems.

70.5 RESIDENTIAL HEAT-GAIN FACTORS

Heat gain occurs in the cooling season when the building is cooler than the outside. Figure 70-2 illustrates common types of heat gain. The same factors that affect heat loss also affect heat gain:

- Transmission gains
- Infiltration gains
- Ventilation gains
- Duct gains

However, there are additional factors that play an important role in heat gain:

- Solar gain through glass
- Internal heat gain from lights, machines, and appliances
- Internal gain from people
- Latent heat gain required for dehumidification

Solar Gain

Solar gain is radiant heat gained from sun shining in through glass. Solar gain varies with the direction of the glass, the latitude of the building, the amount of external shade, and even the time of day. All directions have some solar gain. Northern-facing glass has very little solar gain because the sun never shines directly into northern-facing glass. In commercial load calculations, solar gain is determined separately from the transmissive gains through the windows. Residential calculations, like Manual J, combine the transmissive and solar gains into a single factor.

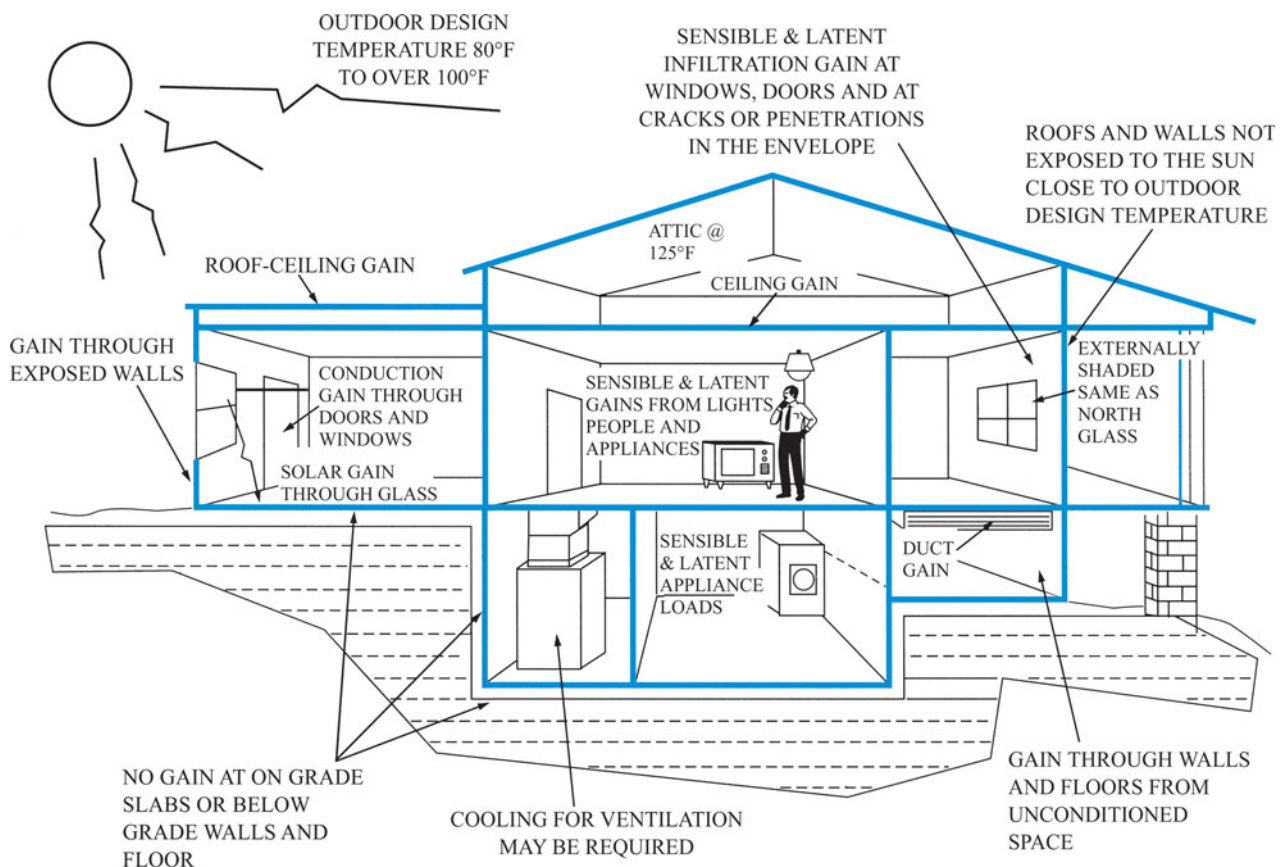

Figure 70-2 Summer cooling loads. (Courtesy of Air Conditioning Contractors of America (ACCA). Copyright ACCA.)

Internal Gain from Lights, Machines, and Appliances

Lights, machines, and appliances all create heat. In many commercial applications, the internal gain exceeds the gain from the walls, ceilings, and floors. Because of this, many commercial buildings need air conditioning even when it is cool outside. The internal light and appliance gains in a typical residence are much smaller. For years, these gains were estimated at 1,200 BTU/hr for a residence. Typically, this amount was added to the kitchen gain. Manual J, 8th edition, has a much more complete listing of appliances and their associated heat gain. The internal gain is still much smaller in residential buildings than in commercial buildings, but it is large enough to warrant a careful assessment.

Internal Gain from People

People produce heat. The gain from people in a theater is usually the major gain for that building. The gain from people in residential buildings is much smaller. The amount of heat produced by each person varies with activity level. Sedentary people add approximately 300 BTU/hr in total heat gain, while people engaged in heavy work can produce approximately 1,500 BTU/hr in total heat gain.

Latent Heat Gain Required for Dehumidification

A big difference between heating loads and air-conditioning loads is that air conditioning also involves dehumidification in most parts of the country. The amount of system capacity devoted to changing the air temperature is called sensible load. The amount of equipment capacity required to remove water from the air is called a latent load because the energy required for condensing water on the evaporator coil does not change the temperature of the air. When an air conditioner is operating with a large latent load, the temperature difference between the return and supply air is less than when it operates with a large sensible load.

In commercial buildings, the latent load from internal machines and people is often the major portion of the building's latent load. In residential buildings, the latent load is largely determined by the grains of water difference between the outdoor air and the indoor air, the amount of infiltration, and the amount of ventilation.

Air-conditioning systems have both a sensible cooling capacity and a latent cooling capacity. Sizing a system to handle the latent load is extremely important in humid areas of the country. Mold and mildew problems can be created if a system with a low latent cooling capacity is installed in a humid area.

TECH TIP

Oversizing an air-conditioning unit reduces its latent cooling capacity. Units that operate for only short periods of time do not run long enough to remove much water from the air, so they have a lower effective latent cooling capacity.

70.6 HOUSE ORIENTATION AND SOLAR GAIN

East-facing windows have a high solar heat gain in the morning, west-facing windows have a high solar gain in the afternoon, and south-facing windows receive solar radiation all day. Northern windows receive no direct solar gain. Most houses have at least one side that has more windows and glass than the other sides. The direction the house is facing will significantly affect the heat gain for cooling load calculations because of the difference in solar heat gain. The amount of heat gained from the floor and ceiling will not change as the house is rotated to face north, south, east, and west.

The effect of house orientation on heat gain will be demonstrated using the house floor plan shown in Figure 70-3. This house has 40 ft² of glass on the front, 75 ft² on the back, 13 ft² on the right side, and 24 ft² on the left side. The table in Figure 70-4 compares the solar load when the house faces south and when the house faces east. The solar gain nearly doubles from 13,400 BTU/hr when facing south to 25,920 BTU/hr when facing east.

70.7 THERMAL CONDUCTIVITY

All materials have different levels of thermal conductivity. The thermal conductivity of different materials is compared using *k* values. A *k* value states the amount of heat that will transfer through each square foot of material for each inch of thickness for every degree in temperature difference. It is expressed in BTU/hr, per square foot of area, per inch thickness, per °F of temperature difference (TD). Materials with high *k* values transmit heat more easily than materials with low *k* values. Figure 70-5 compares the thermal conductivities of common building materials.

70.8 THERMAL RESISTANCE

Thermal resistance is just the opposite of thermal conductance. A material with a low thermal conductance will have a high thermal resistance. The thermal resistance of materials is compared using *R* values. *R* is the number of hours it takes 1 BTU to pass through 1 ft² of material with a 1°F TD. R11 means it takes 11 hr for 1 BTU to pass through 1 ft². R32 means it takes 32 hours for 1 BTU to pass through 1 ft². A high *R* value indicates low heat flow rates.

R values are cumulative. The resistance of several components of a wall may be added together to obtain the total resistance. For example, a wall that has an exterior siding with an *R* value of 0.5, sheathing with an *R* value of 5.0, insulation with an *R* value of 11.0, and an interior surface with an *R* value of 0.5 would have a total *R* value of 17: $0.5 + 5 + 11 + 0.5 = 17$. The *R* value is useful for comparing different types of insulation. Figure 70-6 lists the *R* values of some common building materials.

70.9 U VALUES

The *U* value of a material is defined as the quantity of heat in BTU that will flow through 1 ft² of material in 1 hr with a 1°F TD. The *U* value of any part of a structure is the total

Figure 70-3 Basic residential floor plan.

Facing Direction		South			East			
		Factor	Area	BTU Gain	Direction	Factor	Area	BTU Gain
Front	South	100	40	4,000	East	200	40	8,000
Right	East	200	13	2,600	North	40	13	520
Back	North	40	75	3,000	West	200	75	15,000
Left	West	200	24	4,800	South	100	24	2,400
Total Solar Gain				13,400	Total Solar Gain			25,920

Figure 70-4 The solar load for this house nearly doubles when it faces east instead of south.

heat transfer coefficient for that component. The U value is the reciprocal of the component's R value. For example, if a material had a resistance of R-5, its U value would be 0.2: $\frac{1}{5} = 0.2$. In the example of the wall with a total R value of 17, its U value is 0.06: $\frac{1}{17} = 0.06$ (rounded). The U value gives the BTU/hr per 1 ft² of that component per TD. In this case, 0.06 BTU/hr will transfer through each ft² of wall for every 1°F TD.

70.10 HEAT TRANSFER MULTIPLIERS—HTM

U values give the heat transfer for each degree of temperature difference between the inside and outside temperatures. Heat transfer multipliers (HTMs) give the heat transfer for a specific temperature difference. As the temperature

R-13	Exterior walls/basement walls	15, 23	3.5
R-15	Exterior walls	15	3.5
R-19	Attics/exterior walls/crawlspaces	15, 23	6.25
R-21	Attics/exterior walls	15, 23	5.5
R-30	Attics	16, 24	9.5
R-38	Attics	16, 24	12

Note: Insulation comes both faced and unfaced, in rolls and batts.

Figure 70-6 Value of common building materials.

difference increases, so does the rate of heat transfer. HTMs are calculated by multiplying the U value times the temperature difference. In the example of the R-17 wall with the U value of 0.06 per ft², the HTM for heating with a 50°F TD between outside and inside would be 3 BTU/hr per ft²: $0.06 \text{ BTU/hr/}^\circ\text{F per ft}^2 \times 50^\circ\text{F} = 3 \text{ BTU/hr per ft}^2$. Removing the terms can simplify the math: $0.06 \times 50 = 3$.

70.11 STORAGE AND DAILY RANGE

The temperature difference used for determining most heat loss HTMs is simply the difference between the inside and outside temperature. The temperature difference used for determining heat gain HTMs is called the effective temperature difference. The effective temperature difference takes into account the temperature swings throughout the day and thermal storage in some parts of a building, such as attics.

Storage

When the sun shines in a window, its radiant heat is stored when it reaches the interior surfaces of the house and later gradually heats room air. The same kind of action occurs on the exterior of structures. Radiant heat from the sun warms the surfaces and is stored. Gradually, at a later time, the heat reaches the interior, where it warms the interior air. The net effect of storage is to delay and smooth out solar loads. The delayed effect of the sun's load is incorporated in the procedures used for calculating heat gain.

Daily Range

The difference between the average high and low temperatures is the daily range. The high usually occurs late in the afternoon and the low at about daybreak. The daily range affects the cooling load since a low night temperature can reduce the daytime load due to the storage factor. The daily range factors are given for three ranges: low, medium, and high. The low daily range applies to climates where the difference between the high and low temperatures for the day is 15°F or less. This means there is less natural cooling effect to take advantage of. Areas with a low daily range have the highest effective temperature differences and therefore the highest heat-gain HTMs. The medium daily range applies to climates where the difference between the high and low temperatures for the day is between 16°F and 25°F. These areas can take advantage of some natural cooling. The high daily range applies to climates where the difference between the high and low temperatures for the day is greater than 25°F. This means there is a large natural cooling effect to take advantage of. Areas with a high daily range have the lowest effective temperature differences and therefore the lowest heat-gain HTMs.

Cooling Temperature Difference Versus Design Temperature Difference

The design temperature difference is the difference between the outside and inside design temperatures. The outside design temperature is taken from weather data tables; the inside design temperature is typically 75°F for cooling and 70°F for heating. The cooling temperature difference

is the temperature difference across a building component after taking into consideration factors like thermal storage and daily temperature range. The temperature of the surface of most roofs in the summer is considerably higher than the outdoor temperature. This makes the cooling temperature difference for most ceilings greater than the temperature difference between inside and outside. The cooling temperature difference across walls is often less than the difference between inside and outside because of the natural cooling effect of the daily range.

70.12 OUTSIDE DESIGN CONDITIONS

The outdoor temperature used for determining the temperature difference is not the coldest possible day in the winter or the hottest possible day in summer. The outside design conditions are selected from ASHRAE weather data. The data are assigned a percentage that represents the percentage of time during the year that the temperature exceeds that temperature. Manual J uses 99 percent for heating. This means that 99 percent of the time, the temperature will be above the heating design temperature. The temperature should dip below the heating design temperature for only 88 hr a year. Manual J uses 1 percent for cooling. This means that only 1 percent of the time will the temperature be above the cooling design temperature. The temperature should exceed the heating design temperature for only 88 hr a year. Using the 99 percent and 1 percent conditions prevents excessive oversizing of the equipment to handle a temporary high load. The recommended design temperatures are based on the average temperature of an entire day. Although people tend to think of the highs and lows they hear on the news, these temperatures typically only last for a few hours and do not represent the entire day.

TECH TIP

The design temperature for any locale is based on a 10-year average based on data provided by the U.S. Weather Service. Over time, a design temperature for a locale may vary to match the data collected.

70.13 MANUAL J, 8TH EDITION, WORKSHEET

The Manual J worksheet is like a computer spreadsheet, only in handwritten form (Figure 70-7). It helps organize the data and values for the many calculations required to perform an accurate heat load study. Rows 1–5 across the top contain information about the size of the house or room and the amount of exposed wall. This is shown in Figure 70-8 in yellow. The large block of columns on the left-hand side of the form are for listing the types of materials used and their corresponding heat-transfer multipliers. This is shown in Figure 70-8 in blue. The materials are assigned construction numbers in Manual J to make referencing them easier. The next block over is for calculating the heat loss and heat gain for the entire house. This is shown in Figure 70-8 in green.

Figure 70-7 Worksheet for Manual J, 8th edition. (Courtesy of Air Conditioning Contractors of America (ACCA). From Manual J 8th Edition. Copyright ACCA.)

1		Name of Room				Entire House						
2		Running Feet of Exposed Wall										
3		Ceiling Height At Walls (Ft) and Gross Wall Area (SqFt)										
4		Room Dimensions (Feet) and Floor Plan Area (SqFt)										
5		Ceiling Slope (Degrees) and Gross Ceiling Area										
		Type of Exposure	Const. Number	Panel Faces	HTM Htg. Cig.	Area or Length	Btuh Heating S-Cig. L-Cig.			Area or Length	Btuh Heating S-Cig.	
6a	Windows and Glass Doors	a										
		b										
		c										
6b	Skylights	a										
		b										
7	Metal Door	a

		Sensible Gain		Btuh								
		Latent Gain		Btuh								
13	Internal	a	Occupants at 230 and 200 Btuh			#				#		
		b	Scenario Number									
		c	Default Adjustments									
		d	Individual Appliances									
		e	Plants									
14	Subtotals	Sum lines 6 through 11a + line 12 + line 13										
15	Duct Loads	ELF-Loss and ELF-Gain										
		Latent Gain										
16	Ventilation Loads	Vent CFM			Exh							
17	Winter Humidification load	Gal / Day										
18	Piping Load											
19	Blower Heat											
20	Total Load	Sum lines 11b + lines 14 through 19										

The rest of the blocks are for calculating the heat loss and gain for each individual room. This is shown in Figure 70-8 in purple. Each of these blocks has columns for area, heating, and sensible cooling. The area of each material listed in the area column is multiplied by the HTMs for heating and cooling found on the left-hand side of the form. The answers are written in the heating and cooling columns. Totals are tabulated at the bottom of each column.

TECH TIP

There are many multipliers in Manual J that are decimal numbers with two digits to the right of the decimal. There is no reason to keep values in the BTU loss and gain columns in decimal form. A tenth of a BTU has no practical effect on the size of the equipment. For simplicity's sake, most designers round off the BTU loss and gain to whole numbers. Many round to the nearest hundred BTUs because equipment is sized in thousands of BTUs. For example, a BTU/hr loss of 2,517.6 would be rounded to either 2,518 for whole numbers or simply 2,500 for even hundreds.

70.14 MANUAL J TABLES

At this point, the reader may be thinking that using a quick-and-dirty method is beginning to look pretty good. Keeping track of effective temperature differences, R values, U values, and heat-transfer multipliers can appear to be a difficult task. The purpose of Manual J is to do most of the heavy lifting for you. The tables in Manual J, 8th edition, list heat-transfer multipliers for many different construction types. Factors like the direction that windows face, the daily range, and equivalent temperature differences have all been factored in for you. All you have to do is learn to use the tables. We are going to go through an example whole-house calculation using the plan in Figure 70-3. An abbreviated worksheet will be used that only shows the items being used. The necessary tables will be described along the way.

70.15 WEATHER DATA TABLES 1A AND 1B

Table 1A contains weather data for cities throughout the United States and Canada. The table is organized with cities in the United States in the first part of the table and cities

1	Name of Room					Entire House							
2	Running Feet of Exposed Wall												
3	Ceiling Height At Walls (Ft) and Gross Wall Area (SqFt)												
4	Room Dimensions (Feet) and Floor Plan Area (SqFt)

Figure 70-8 Major sections of the Manual J, 8th edition, worksheet. (Courtesy of Air Conditioning Contractors of America (ACCA). From Manual J 8th Edition. Copyright ACCA.)

in Canada in the second part. The states and provinces are listed in alphabetical order, and the cities are listed under their state in alphabetical order. The most important data found in this table are the following:

- **Latitude** Latitude is used to calculate shade from overhangs above windows.
- **Heating 99% dry bulb** Heating 99% dry bulb is used for the heating outdoor design temperature.
- **Cooling 1% dry bulb** Cooling 1% dry bulb is used for the cooling outdoor design temperature.
- **Design grains RH** Design grains RH lists the grains of difference between inside and outside in the summer. This is used for calculating the latent cooling load. Manual J has three columns, one each for 55%, 50%, and 45% indoor relative humidity.

Table 1B lists the same information as Table 1A but has more locations in the states of Arizona, California, Hawaii, and Nevada.

For our example, the house will be located in Selma, Alabama. The winter design for Selma is 26°F and the summer design temperature is 95°F (Figure 70-9). The design grains of difference will be 49 grains for 50 percent relative

humidity. The winter design temperature difference will be 44°F: 70°F – 26°F = 44°F. The summer design temperature difference will be 20°F: 95°F – 75° = 20°F. The house will be facing east and the daily range is medium.

70.16 ROOM DIMENSIONS

The first line is for the room name—in this case it is the entire house. The running feet of exposed wall is the length of wall that is exposed to the outside. Only walls that are exposed to the outside are listed. For example, the master bathroom has only 5 ft of exposed wall. The house as a whole has two walls of 32 ft and two walls of 28 ft, for a total of 120 ft. The ceiling in our example will be a standard ceiling: 8 ft high with no slope. Figure 70-10 shows this part of the form completed.

70.17 FENESTRATION HEAT LOSS TABLES 2A AND 2B

In Manual J, fenestration refers to anything that light can pass through, including windows, skylights, and glass doors. Table 2A lists U values for generic windows, skylights, and glass doors. These U values are used to construct heat-loss HTMs.

Construction Numbers 1 Through 7 Window and Glass Door Assemblies Reference Area = Area of Rough Opening (SqFt). Bold Face denotes U-Values used for Tables 3A, 3B, 3F and 3G.	Type of Frame Construction			
	Metal No Break	Metal With Break	Wood, Wood With Metal Clad or Vinyl	Insulated Fiberglass
Number 1 — Clear, Heat Absorbing or Reflective Glass	U-Value			
A. Single pane operable window or sliding glass door	1.27	1.08	0.50	0.81
B. Single pane window, fixed sash	1.13	1.07	0.98	0.94
C. Single pane operable window with storm	0.87	0.65	0.57	0.49
D. Double pane operable window or sliding glass door	0.87	0.65	0.57	0.49
E. Double pane window, fixed sash	0.69	0.63	0.50	0.53
F. Triple pane window, fixed sash	0.55	0.48	0.42	0.40
G. Products rated and labeled by the NFRC (see Table 2B-1)	Refer to label, NFRC Directory or manufacturer's engineering data.			
Number 2 — Double Pane Low-e Glass Designed For Cold Climate (Emissivity of Low-e coating = 0.60)	U-Value			
A. Operable window or sliding glass door	0.84	0.63	0.55	0.47
B. Window with fixed sash	0.67	0.60	0.51	0.51
C. Products rated and labeled by the NFRC (see Table 2B-1)	Refer to label, NFRC Directory or manufacturer's engineering data.			
Number 3 — Double Pane Low-e Glass Designed For Cold Climate (Emissivity of Low-e coating = 0.40)	U-Value			
A. Operable window or sliding glass door	0.82	0.61	0.53	0.45
B. Window with fixed sash	0.64	0.55	0.51	0.49
C. Products rated and labeled by the NFRC (see Table 2B-1)	Refer to label, NFRC Directory or manufacturer's engineering data.			
Number 4 — Double Pane Low-e Glass Designed For Cold Climate (Emissivity of Low-e coating = 0.20 or less)	U-Value			
A. Operable window or sliding glass door	0.77	0.56	0.47	0.41
B. Window with fixed sash	0.59	0.52	0.45	0.43
C. Products rated and labeled by the NFRC (see Table 2B-1)	Refer to label, NFRC Directory or manufacturer's engineering data.			
Number 5 — Jalousie Window	U-Value			
A. Jalousie window only	1.27	~	~	~
B. Jalousie window with storm	0.69	~	~	~
Number 6 — Projected Window Assemblies	U-Value			
A. Bay window with any fixed sash window listed above	Multiply flat panel, fixed sash U-Value by 1.15.			
B. Garden window with any fixed sash window listed above	Multiply flat panel, fixed sash U-Value by 2.75.			
C. Products rated and labeled by the NFRC (see Table 2B-1)	Refer to label, NFRC Directory or manufacturer's engineering data.			
Number 7 — Glass or Plastic Block	U-Value			
A. Glass block with mortar joints	Use 0.60 U-Value for all products.			
B. Products rated and labeled by the NFRC (see Table 2B-5)	Refer to label, NFRC Directory or manufacturer's engineering data.			

T2A-1

Figure 70-11 Window construction number and U value from Table 2A of Manual J, 8th edition. (Courtesy of Air Conditioning Contractors of America (ACCA). From Manual J 8th Edition. Copyright ACCA.)

In Table 2A, the column on the left describes the type of glass, the number of panes, and the general construction. The column on the right lists the type of frame. To use the table, locate the row in the left column that describes the type of glass and window construction. The U value is listed over on the right under the column that describes the frame style. The windows in our example house are fixed sash, wood frame, double-pane windows with a low e coating of 0.4 emissivity. Figure 70-11 shows the construction number is 3B and the U value is 0.51.

Once the U value has been determined, the HTM is calculated by multiplying the winter temperature difference times the U value. In this case, the HTM would be 22.4 BTU/hr for a winter temperature difference of 44°F: $0.51 \text{ BTU/(hr}^\circ\text{F)} \times 44^\circ\text{F} = 22.4 \text{ BTU/hr}$. The heat loss for the windows is calculated by multiplying this HTM by the area of all the windows (Figure 70-12).

Table 2B is for windows, glass doors, and skylights that are rated by the National Fenestration Rating Council (NFRC). NFRC-rated items have a label that lists important energy performance data, including the U value, solar heat-gain coefficient, and air leakage. For typical windows and glass doors, the HTM can be calculated by multiplying the U value listed on the window by the winter temperature

difference. Table 2B lists formulas to help determine the HTM values for more complicated fenestrations, such as bay windows and skylights.

70.18 FENESTRATION HEAT-GAIN TABLES 3A–3I

Tables 3A–3I provide HTM values for heat gain, including solar gain. The large number of tables is for specifying the amount of external shade, the type of fenestration, and the load procedure used. Tables 3A–3D are used for the average load procedure. Tables 3F–3I are used for the peak load procedure. Table 3E is used to adjust the HTM for factors such as overhang, foreground reflectance, and latitude. We will only be discussing Tables 3A–3D. Briefly, the tables are as follows:

- **3A** Generic windows and glass doors with no external sun screen
- **3B** Generic windows and glass doors behind an external sun screen
- **3C** Generic skylights
- **3D** NFRC-rated windows and doors

Figure 70-12 The heat loss portion of line 6a of the Manual J worksheet is completed.

Tables 3A and 3B both have multiple pages. In Table 3A, each page covers a different type of glass: clear, heat absorbing, reflective, and glass block. In Table 3B, each page covers a different amount of external sun screen: 15, 25, 35, and 45 percent. Each page in both tables is organized into three columns: single pane, double pane, and triple pane. Each column is further divided into columns for temperature difference and rows for the direction the window faces. In our example, the HTM for a double-pane window with no external sun screen, heat-absorbing glass, and no internal shade would be found in Table 3A, page 2. To find the HTM for the east- and west-facing windows in the house, first look at the large row at the top of Table 3A, page 2, described as *No internal shade*. Find the column in the middle listed as *Double pane*. The HTM is at the intersection of the row for *East or west* and the 20 column (the summer design temperature difference). In this case, the HTM is 52 (Figure 70-13). The HTM values for the north-facing and south-facing windows are found in a similar manner. The HTM for the north-facing windows is 20 and the HTM for the south-facing windows is 29. The heat gain through the windows is then calculated by multiplying these HTM values by the area of the windows. (The heat gain for each window is recorded in the sensible column as shown in Figure 70-14).

70.19 HEAT LOSS AND GAIN FOR OPAQUE SURFACES, TABLES 4A–4C

Opaque surfaces are simply surfaces that light will not pass through, including doors, walls, floors, and ceilings. Tables 4A and 4B are used for the average load procedure; Tables 4C and 4D are used for the peak load procedure. We will only be discussing Tables 4A and 4B. Table 4A covers several pages and is organized into construction numbers:

- 11 Wood and metal doors
- 12 Frame walls and partitions
- 13 Block walls and partitions
- 14 Alternative constructions of walls and partitions
- 15 Basement walls
- 16 Ceiling under attic and knee walls
- 17 Ceiling on exposed beams
- 18 Ceiling below roof joists
- 19 Floor over enclosed crawlspace or unconditioned basement

- 20 Floor over open crawlspace or garage
- 21 Basement floor
- 22 Slab on grade

Heat Loss

The tables in 4A all include U values. The heat-loss HTM is calculated by multiplying the U value by the heating temperature difference.

Heat Gain

The tables for construction numbers 11, 16, 17, 18, 19, and 20 list a cooling temperature difference. The cooling temperature difference and the U value are used to construct a heat-gain HTM. The tables for construction numbers 12, 13, 14, and 15 do not give a cooling temperature difference but list a group number instead. The group number is used to look up the cooling temperature difference using Table 4B. The cooling temperature difference and the U value are then used to construct a heat-gain HTM.

Figure 70-14 The heat gain portion of line 6a of the Manual J worksheet is completed. (Courtesy of Air Conditioning Contractors of America (ACCA). From Manual J 8th Edition. Copyright ACCA.)

Door

In our example, the U value for a polyurethane core metal door would be 0.29 (Figure 70-15). The heat loss HTM for this door in our house with a 44°F winter temperature difference would be 12.8: $0.29 \times 44 = 12.8$. The heat loss through the

door would be calculated by multiplying this HTM by the area of the door, 20 ft². For a 20 degree summer temperature difference and a medium daily range the table shows the cooling HTM as 31. The heat gain is calculated by multiplying this HTM by the area of the door. Figure 70-16 shows the calculations for both heating and cooling.

Figure 70-16 Door calculation on line 7 completed on Manual J worksheet.

Walls

The frame walls in our house are construction number 12B-4b: wood frame wall with R-11 insulation, R-4 insulating sheathing, and a brick veneer. They have a U value of 0.073 and are listed in Group J (Figure 70-17). The heating HTM is 3.2: $0.073 \times 44 = 3.2$.

Our house is in a climate with a medium daily range, and the summer design temperature difference is 20°F. Table 4B shows that group J would have a cooling temperature difference of 16.4 (Figure 70-18). The heat-gain HTM is calculated by multiplying the U value from Table 4A (Figure 70-17) by the cooling temperature difference from Table 4B (Figure 70-18): $\text{HTM} = 0.073 \times 16.4 = 1.2$.

The heat loss and gain for the walls are calculated by multiplying the HTM by the net wall area. The net wall area is the wall area left after subtracting the window and door areas from the gross wall area. In our example, there is a total of 172 ft² of doors and windows. The gross wall area is 960 ft². The net wall area is $960 \text{ ft}^2 - 172 \text{ ft}^2 = 788 \text{ ft}^2$ net wall area. Figure 70-19 shows the wall calculations.

Ceiling

The ceiling in our example has a construction number of 16B-30: ceiling under a vented attic with R-30 insulation.

The U value is 0.032. The heat-loss HTM is 1.4: $44 \times 0.032 = 1.4$. Our house is located in an area with a medium daily range and has a design temperature difference of 20°F in the summer. The table shows a cooling temperature difference of 55°F (Figure 70-20). The cooling HTM would then be 1.8: $0.032 \times 55 = 1.8$. Figure 70-21 shows the ceiling calculations.

Floor

The slab-on-grade construction number 22 is unique in that it lists F values rather than U values. The HTM is calculated the same: F value times the heating temperature difference equals the HTM. The concrete slab floor in our example has a construction number of 22A-ph: no insulation on heavy, moist soil. It has an F value of 1.358 (Figure 70-22). The heat-loss HTM for a house with a heating temperature difference of 44°F would be 60: $44 \times 1.358 = 60$ (approximately). However, the resulting HTM is not for square feet but for linear feet of exposed edge. So the heat loss of the floor is $60 \times 120 = 7,200 \text{ BTU/hr}$. Figure 70-23 shows the floor calculations.

Tables for construction numbers 21 and 22 do not include any heat-gain information because there is no heat gain from a concrete floor on the ground.

70.20 INFILTRATION TABLES 5A-5E

Tables 5A and 5B show a simplified method of estimating the amount of infiltration in a house. Tables 5C-5E offer a more detailed method of calculating the amount of infiltration air based on specific construction details. We will only be discussing Tables 5A and 5B. Table 5A is for homes with three or four exposures. Most single-family houses fall into this category. Table 5B is for homes with only one or two exposures. This would apply to many apartments, condominiums, or townhomes.

Tables 5A and 5B are used in the same manner because they are organized identically. These tables estimate the number of air changes per hour based on general construc-

tion criteria. An air change occurs when all the air in a building has been replaced with new, outside air. The phrase "air changes per hour" describes how often this occurs. The amount of infiltration can be calculated by multiplying the total house volume by the number of air changes per hour. For example, in a 1,000-ft² house with an 8-ft ceiling, the volume is 8,000 ft³: $1,000 \times 8 = 8,000$. If this house had an air change rate of 1.5 air changes per hour, the amount of infiltration would be $1.5 \times 8,000 = 12,000$ ft³/hr.

Each table has two sections: one for heating air changes and one for cooling air changes. Heating air changes tend to be higher than cooling air changes, primarily because the average wind velocity in the winter is assumed to be higher than in the summer. Using the general guides at the bottom

of the page, the house is analyzed as being tight, average, or leaky. Select the description that best fits the house. The floor area of the house is listed in columns. The value for the average number of air changes is at the intersection. For our example house with 876 ft², the table shows a winter air change rate of 1.05 and a summer air change rate of 0.55 (Figure 70-24). Converting these air changes to airflow:

$$\text{Winter } 896 \times 8 \times 1.05 = 7,526 \text{ ft}^3/\text{hr} (7,526 \text{ ft}^3/\text{hr})/60 \\ = 125 \text{ ft}^3/\text{min}$$

$$\text{Summer } 896 \times 8 \times 0.55 = 3,942 \text{ ft}^3/\text{hr} (3,942 \text{ ft}^3/\text{hr})/60 \\ = 66 \text{ ft}^3/\text{rom}$$

The infiltration loss and the sensible infiltration gain are calculated by multiplying the design temperature difference by 1.1 and by CFM of infiltration air because it takes approximately 1.1 BTU to raise 1 CFM 1°F. The infiltration loss for our example house is:

$$\text{Infiltration loss } 44^\circ\text{F} \times 1.1 \text{ BTU/hr/CFM} \times 125 \text{ CFM} \\ = 6,050 \text{ BTU/hr}$$

$$\text{Sensible infiltration gain } 20^\circ\text{F} \times 1.1 \text{ BTU/hr/CFM}^\circ \times 66 \text{ CFM} \\ = 1,452 \text{ BTU/hr}$$

The latent infiltration is calculated by multiplying 0.68 × grains difference × CFM. In our example for Selma, Alabama there is a 49 grain difference at the summer design condition of 50% relative humidity. The result is 0.68 × 49 grains × 66 CFM = 2200 Btu/hr.

The infiltration loss and gain is distributed throughout the house based on the ratio of the outside wall area for that room compared to the entire outside wall area. This is called the wall area ratio, or WAR. The WAR in our example is 1.0 because we are calculating the load for the entire house. Figure 70-25 shows the infiltration calculations.

20	Total Load		Sum lines 11b + lines 14–19								

Figure 70-19 Wall calculations on line 8 completed on Manual J worksheet.

We will calculate the WAR for the kitchen to show how the WAR is calculated for a room. The total outside wall area for our example house is 960 ft². The outside wall area for the kitchen is 216 ft²: 27 ft \times 8 ft = 216 ft². The WAR for the kitchen is 216 ft²/960 ft² = 0.225. This factor would be multiplied by the total infiltration loss and gain for the house to determine the infiltration loss and gain for the kitchen.

70.21 INTERNAL LOADS, TABLES 6A AND 6B

Table 6A contains general information on sensible and latent loads added by appliances and people. It starts with the same 1,200 BTU/hr for appliances that has been used for 30 years but then offers other scenarios. A brief description is provided with each scenario to help determine which is the most appropriate. Extra information is also provided for adjusting the appliance allowance. For example, most families today would require the 1,400 additional BTU/hr for using electronic entertainment equipment.

Notice that some loads add to both the sensible and the latent load. People are an example of a load that is both sensible and latent. Plants add only to the latent load. People are estimated at one person per bedroom plus one

more person. Our example house has two bedrooms, so we will use three people. For the appliances we will use Scenario 1 with 2,400 BTU/hr (Figure 70-26). The internal load calculations are shown in Figure 70-27.

Table 6B has information on specific appliances. This table can be used to produce a more detailed estimate of internal appliance load when the specific types of appliances being used are known.

70.22 SUBTOTAL

The subtotal sums all the loads for heat loss, sensible heat gain, and latent heat gain. The subtotal does not include duct load, ventilation load, winter humidification load, piping load, or blower heat. The subtotal amounts will be used to calculate the duct loss and gain. The subtotal calculations for the example are shown in Figure 70-28.

70.23 DUCT LOADS, TABLES 7A–7L

The duct loss in heating and duct gain in cooling take two forms: heat transfer between the duct and the surrounding air and air leakage in the duct. The heat gain that can occur from putting an air-conditioning duct in a hot attic is

Construction Number 16 Ceiling Under Attic or Attic Knee Wall

T4A-18

Figure 70-20 U value and cooling temperature difference for ceiling from Table 4A, construction number 16. (Courtesy of Air Conditioning Contractors of America (ACCA). From Manual J 8th Edition. Copyright ACCA.)

obvious. Less obvious is the large heat gain that can occur from a leaky return in the same hot attic. In fact, the air leak in the return is probably a more significant heat gain. The duct loss and gain tables take the type of duct system, duct sealing, duct location, the temperature of the air in the duct, and the temperature of the air around the duct into account. As a result, the duct heat-loss and heat-gain tables cover over 40 pages. However, you will normally only be using two of these pages for any particular job.

The first page is like a table of contents for the other pages. Descriptions of the duct location, the type of return, and the type of supply are used to select the appropriate table. In our example, a sealed radial duct system in a 120°F vented attic would use Table 7C-RS (Figure 70-29). The following pages all work similarly. The box in the upper left-hand corner describes the duct system, outlined in green

on Figure 70-30. The long vertical box on the right-hand side of the page is used for determining the heat loss, outlined in red on Figure 70-30. The box in the middle of the left-hand column is for determining sensible heat gain, outlined in blue on Figure 70-30. The box in the lower left-hand corner is for determining latent heat gain, outlined in purple on Figure 70-30.

Duct Loss

The outdoor air temperature, the heated supply-air temperature, and the floor area are used to determine the duct loss. In our example, a system with a supply air temperature of 100°F and an outdoor air temperature of 30°F in a 1,000-ft³ house would have a duct loss factor of 0.08 (Figure 70-31). This factor is multiplied by the heat loss for the entire house to

Figure 70-25 Infiltration calculations for Manual J, line 12.

determine the BTU/hr duct loss. In our example, the duct loss for the house would be $20,686 \text{ BTU/hr} \times 0.08 = 1,655 \text{ BTU/hr}$ duct loss. The duct loss tables assume a duct insulation value of R-6. Factors for other insulation values are given at the bottom of the duct loss column (Figure 70-32).

Sensible Duct Gain

There are two types of duct gain: sensible and latent. The outdoor air temperature and house size are used to determine the sensible duct gain. In our example, a system in a 1,000 ft³ house with an outdoor air temperature of 95°F would have a sensible duct gain factor of 0.12 (Figure 70-33). The sensible duct gain for our example house would be $14,217 \text{ BTU/hr} \times 0.12 = 1,706 \text{ BTU/hr}$ sensible duct gain. The sensible duct gain tables assume a duct insulation value of R-6. Factors for other insulation values are given at the bottom of the sensible duct gain box (Figure 70-32).

Latent Duct Gain

Unlike the duct loss or the sensible duct gain, the latent duct gain tables give a BTU/hr amount instead of a factor. The grains of water difference and house size are used to

determine the latent duct gain. For our example, a system in a 1,000-ft³ house with a grains of water difference of 50 grains would have a latent duct gain of 283 BTU/hr (Figure 70-30). Figure 70-35 shows all the duct load calculations.

70.24 TOTAL LOAD

The last line on the form is for tallying the total load. There will be three totals: heat loss, sensible heat gain, and latent gain. These are the design loads that will be used to select the equipment. Figure 70-36 shows the total calculations for our example house. Ideally, the equipment should be sized as close to the total design load as possible without oversizing. Remember that most of the time the equipment will be operating at loads that are less than the design condition. In effect, the equipment is already oversized for most of its operating life and does not need to be oversized any further. Oversized equipment operates less efficiently than undersized equipment. Furnaces, air conditioners, and heat pumps all must operate for several minutes before they are operating at their peak efficiency. A unit that only operates for 2 minutes at a time never operates at its peak efficiency.

Appliance, Equipment and Lighting Loads			
Default Appliance Load	Sensible Btuh	Latent Btuh	Notes
Refrigerator and range with vented hood.	1,200	~	1,200 Btuh applied to the kitchen.
Scenario Options			
1) Refrigerator, range with vented hood, dish washer, clothes washer and vented clothes dryer, electronic equipment and lighting allowance.	2,400	~	1,000 Btuh for the kitchen, 500 Btuh for the utility room, 900 Btuh allowance for a TV or computer and a few lighting fixtures.
2) Two refrigerators or one refrigerator and one freezer, dish washer, range with vented hood, clothes washer and vented clothes dryer, electronic equipment and lighting allowance.	3,400	~	2,000 Btuh for the room or rooms equipped with a refrigerator, 500 Btuh for the utility room, 900 Btuh allowance for a TV or computer and a few lighting fixtures.
Adjustment Options			
A) Cooking range not equipped with a hood that is vented to outdoors, or an unvented dishwasher operating during the late afternoon in mid summer, or simultaneous use of unvented range and dishwasher.	+ 850	+ 600	Light duty cooking, 25 percent of the available range capacity used for 15 to 20 minutes. One dishwasher-cycle load spread over a two hour recovery period.
B) Water bed heater (400 Watts, 33 percent duty cycle).	+ 450	~	Apply to each bedroom equipped with a water bed .
C) Ceiling fan (75 Watts).	+ 250	~	Apply to the room where the fan is located.
D) Large family using TV's stereos, computers and laundry room during the late afternoon in mid summer.	+ 1,400	~	This is an additional 410 Watt allowance for A/V or computer equipment.
E) Allowance for above average lighting load.	+ 1,705	~	Five 100 watt lights.
F) Unvented clothes dryer.	Clothes dryers must be vented for air quality and efficiency.		
Assignment			
For room heat gain estimates, correlate the equipment loads with the rooms that contain the equipment (existing construction) or which will logically contain the equipment (working from drawings).			
Internal Loads for Full Time Occupants, Guests and Plants			
Item	Sensible Btuh	Latent Btuh	Notes
Full Time Occupant	230	200	Occupancy = Number Bedrooms + 1
Guest	230	180	Number of guests specified by owner
Each Small Plant	~	10	Less than 12 Inches high
Each Medium Plant	~	20	12 inches to 24 inches high
Each Large Plant	~	30	More than 24 inches high

Figure 70-26 Internal heat load selection from Table 6A. (Courtesy of Air Conditioning Contractors of America (ACCA). From Manual J 8th Edition. Copyright ACCA.)

However, equipment is only available in certain sizes. In our example house, almost any gas or oil furnace will be oversized. Typically, the smallest gas furnaces available have a heat output capacity of approximately 32,000 BTU/hr, and the house only requires 22,341 BTU/hr. A two-stage furnace could solve this problem. The first stage would not be oversized and would allow the equipment to operate efficiently.

The cooling load has two components: sensible and latent. The capacity of air-conditioning equipment varies based on the coil match and airflow. It is important to look at both the sensible and latent capacity when sizing air-conditioning equipment. It would be possible for a piece of equipment to match the total of the sensible and latent loads but not provide enough latent capacity. This house falls in between a 1.5-ton and a 2-ton air conditioner. In general, using the smaller size will give better results for latent cooling, comfort, and operating efficiency because it will run longer. Not all companies make a 1.5-ton system. A 2-ton system would also be acceptable if a system with a variable-speed blower were selected that can operate in

dehumidification mode. This particular house would be a good candidate for a heat pump because the heat loss and heat gain are close to each other in capacity.

TECH TIP

It is important to note that properly sized heating and cooling systems will provide your customers with the best system for their homes. Oversizing causes the system to start and stop too frequently, just like driving your car in stop-and-go traffic. When you drive a car in stop-and-go traffic it does not get as good gas mileage as it does when on the highway. A car driven mostly on the highway will last longer than one that is driven mostly in stop-and-go traffic. That is the same with all equipment, including heating and air-conditioning systems. Therefore, longer periods of operation are better for both the efficiency and life expectancy of all HVAC equipment.

Summary of Default Duct Load Factor Tables			
Location	Supply System	Return System	Table Number
In unvented attic or attic knee wall space above ceiling 16A (150 °F attic). Default for duct in unvented ceiling cavity.	Radial with outlets in center of rooms.	Radial, 400 CFM per return, returns close to air handler.	7A-RN Not sealed 7A-RS Sealed
	Trunk and branch with outlets in center of rooms.	Trunk and branch, 400 CFM per return, returns close to air handler.	7A-TN Not sealed 7A-TS Sealed
In vented attic or attic knee wall space above ceiling 16B (130 °F attic).	Radial with outlets in center of rooms.	Radial, 400 CFM per return, returns close to air handler.	7B-RN Not sealed 7B-RS Sealed
	Trunk and branch with outlets in center of rooms.	Trunk and branch, 400 CFM per return, returns close to air handler.	7B-TN Not sealed 7B-TS Sealed
In vented attic or attic knee wall space above ceiling 16C (120 °F attic).	Radial with outlets in center of rooms.	Radial, 400 CFM per return, returns close to air handler.	7C-RN Not sealed 7C-RS Sealed
	Trunk and branch with outlets in center of rooms.	Trunk and branch, 400 CFM per return, returns close to air handler.	7C-TN Not sealed 7C-TS Sealed
In vented attic or attic knee wall space above ceiling 16D (110 °F attic).	Radial with outlets in center of rooms.	Radial, 400 CFM per return, returns close to air handler.	7D-RN Not sealed 7D-RS Sealed
	Trunk and branch with outlets in center of rooms.	Trunk and branch, 400 CFM per return, returns close to air handler.	7D-TN Not sealed 7D-TS Sealed
In vented attic or attic knee wall space above ceiling 16E (105 °F attic).	Radial with outlets in center of rooms.	Radial, 400 CFM per return, returns close to air handler.	7E-RN Not sealed 7E-RS Sealed
	Trunk and branch with outlets in center of rooms.	Trunk and branch, 400 CFM per return, returns close to air handler.	7E-TN Not sealed 7E-TS Sealed
In vented attic or attic knee wall space above ceiling 16F (95 °F attic).	Radial with outlets in center of rooms.	Radial, 400 CFM per return, returns close to air handler.	7F-RN Not sealed 7F-RS Sealed
	Trunk and branch with outlets in center of rooms.	Trunk and branch, 400 CFM per return, returns close to air handler.	7F-TN Not sealed 7F-TS Sealed
In unvented cavity below roof joists or in cavity between roof joists (roof construction 18).	Radial with outlets in center of rooms.	Radial, 400 CFM per return, returns close to air handler.	Use Tables 7A to 7F. Use estimated cavity temperature to select a table.
	Trunk and branch with outlets in center of rooms.	Trunk and branch, 400 CFM per return, returns close to air handler.	
In open crawl space or garage.	Radial with outlets at perimeter of rooms.	Radial, 400 CFM per return, returns close to air handler.	7G-RN Not sealed 7G-RS Sealed
	Trunk and branch with outlets in center of rooms.	Trunk and branch, 400 CFM per return, returns close to air handler.	7G-TN Not sealed 7G-TS Sealed
In closed crawl space below insulated floor, no wall insulation.	Radial or trunk and branch with outlets at perimeter of rooms.	Radial or trunk and branch, 400 CFM per return, returns close to air handler.	7H-N Not sealed 7H-S Sealed
In unconditioned basement or closed crawl space with: o No wall or ceiling insulation o Wall insulation only o Wall and ceiling insulation	Radial or trunk and branch with outlets at perimeter of rooms.	Radial or trunk and branch, 400 CFM per return, returns close to air handler.	7I-N Not sealed 7I-S Sealed
Supply runs below slab. Return runs in conditioned space or in attic.	Radial with outlets at room perimeter. No supply leakage. Sealing options apply to the return runs.	Duct runs in conditioned space.	7J-1 No Leakage
		Radial system in attic, 400 CFM per return, returns close to air handler.	7J-2N Not Sealed 7J-2S Sealed
Riser or drop in exterior wall.	Rectangular or round airway.		7K-N Not sealed 7K-S Sealed
		Rectangular or round airway.	7L-N Not Sealed 7L-S Sealed

Figure 70-36 Total load calculations for Manual J worksheet.

UNIT 70—SUMMARY

Heating and air-conditioning equipment operates most efficiently when it is properly sized. The calculations done to determine the amount of heating and cooling required for a particular building are called heat load calculations or a heat load study. Winter calculations are called heat loss, and summer calculations are called heat gain. There are two types of heat gain: sensible and latent. Calculations are necessary to take into account the many variables that affect heat loss and heat gain. The resistance of a material to heat flow is measured in R value. Heat travels more slowly through materials with higher R values. U factors are used to calculate the amount of heat traveling through a building panel. U factors are built by adding up all the R values of the components in a building panel and finding the reciprocal. A panel with a total resistance of R-10 has a U factor of $\frac{1}{10}$, or 0.10. Heat-transfer multipliers, or HTMs, are built by multiplying a panel's U factor by the temperature difference across the panel. A panel with a U factor of 0.10 and a temperature difference of 50°F will have an HTM of 5. The heat transferred through a section of a building is determined by multiplying that panel's HTM by the square-foot area of the panel. The most accepted method for organizing and simplifying heat load calculations is Manual J. Manual J worksheets are like a handwritten spreadsheet. The information is organized in tables that make calculations easier.

UNIT 70—REVIEW QUESTIONS

1. Why are heat load calculations necessary?
2. What is the difference between a shell load study and a room-by-room load study?
3. What advantage is there to doing a room-by-room load study over a shell load study?
4. Why does oversized equipment operate inefficiently?
5. What is the difference between heat loss and heat gain?
6. What is the difference between sensible heat gain and latent heat gain?
7. What is the R value of a material with a thermal conductivity of 2.0 that is 4 in thick?
8. How is a U factor calculated for a building panel built of several different materials?
9. Determine the U value for a wall with the following construction:

Exterior siding	R-0.75
Cavity insulation	R-13
Interior wall	R-0.5
10. How is an HTM calculated?
11. What would the HTM be for a building panel with a U value of 0.8 and a temperature difference of 40°F?
12. What is meant by the temperature daily range?
13. What effect does the daily range have on heat gain?
14. Why is the cooling temperature difference often different from the difference between the indoor and outdoor temperatures?
15. How are the outside design conditions chosen?
16. List some of the differences between residential and commercial load calculations.
17. What is Manual J?
18. Using the table in Figure 70-20, determine the heat-gain HTM for a ceiling with the following specifications:

150°F unvented attic
R-19 insulation
Outside design temperature 90°F
Inside design temperature 75°F
Low daily temperature range
19. What is the heat-gain HTM for a concrete slab on a grade floor?
20. Calculate the heat loss for a concrete slab on a grade floor for a room with the following specifications

10 ft by 15 ft bedroom on corner of house
Two sides exposed
HTM of 40

UNIT 71

Duct Design

OBJECTIVES

Upon completion of this unit, you will be able to:

1. list the three overall goals in duct design.
2. list the different duct design methods.
3. discuss how to determine the duct system design static pressure.
4. explain the difference between design friction loss rate and the actual static pressure loss through a duct.
5. explain how a duct's equivalent length is determined.
6. use a duct calculator to look up the duct size, air velocity, and friction rate.
7. list the criteria for selecting grilles and registers.

71.1 INTRODUCTION

Duct systems are the distribution network for conditioned air to be moved throughout a building. Duct systems are designed to provide conditioned air that matches the needs of the structure. Proper duct system design is critical to the energy efficiency of a building. Duct designers must use information such as heat load calculations, cooling load calculations, equipment selection, and architectural design to produce specialized duct plans for each structure. Technicians need to understand duct systems and airflow to be able to troubleshoot and maintain an HVAC system. Factors that adversely affect system airflow will also have a negative impact on system efficiency and reliability.

71.2 DUCT DESIGN METHODS

The two most common methods of duct design are static regain and equal friction. In the static regain method, the air velocity is reduced at the end of long trunk-duct runs to increase the static pressure. The static pressure increase is calculated to offset the static pressure lost through the run, so the static is regained. This method is primarily applied to large commercial installations and is not used in residential or light commercial applications. In the equal-friction method, the duct is sized to offset differences in duct length. When selecting the duct size, long runs use a lower friction rate than short runs. When applied properly, the equal-friction method produces a well-balanced system, delivering air where it is needed. A practical limitation of equal-friction design is that duct is only available in certain physical sizes. This often forces the designer to choose a duct that is a little larger or smaller than the ideal duct size. Balancing dampers can be added so that final adjustments can be made to produce a well-balanced system.

Two commonly used guides for duct design are the ASHRAE duct design method and the ACCA Manual D. The current Manual D method is a modified equal-friction method because the friction rate is not adjusted for each run. Rather, all runs are designed at a friction rate that

will work for the run with the highest equivalent length. This ensures that the pressure drop through the duct system will not be excessive while keeping the calculations simpler. However, it produces an inherently unbalanced system because all runs are treated the same, even though they have different equivalent lengths. Balancing dampers are a necessity with this design system. To have balanced airflow, the system must be commissioned by taking airflow measurements and making adjustments to the dampers to adjust the airflow through each run. The disadvantage of this system is simply that the system must be operated and balanced after installation to perform well. While this is certainly a step that should be done, many residential systems never undergo a commissioning process. For the remainder of this unit, we discuss the equal-friction method.

71.3 EQUIVALENT LENGTH

The amount of pressure lost through a duct is directly related to its equivalent length. Many runs in a normal residential house will be longer than 100 ft in equivalent length. Every time the air changes direction it loses some of its pressure. This loss in pressure is most commonly stated as equivalent to the pressure loss through a length of duct. An elbow with a large radius will have an equivalent length of approximately 10 ft. This means that the pressure lost when the air moves around this elbow is equivalent to the pressure lost when traveling through 10 ft of pipe. Figures through 71-4 show the equivalent length for several common fittings when duct static and velocity are within the normal range of residential systems.

To find a duct's total equivalent length, add up the trunk duct length to the takeoff, the branch duct length, and the equivalent lengths of all the fittings used from the blower to the register. For example, take a branch duct run on an extended plenum system (Figure 71-5). The trunk duct leaving the plenum is equivalent to 35 ft; the branch takeoff from the trunk duct is another 35 ft. The torpedo boot on the end of the run adds 50 ft. The run has 120 ft of equivalent length in fittings alone. After adding 10 ft for each downstream

Figure 71-1 Equivalent lengths: supply- and return-air plenum fittings.

Figure 71-2 Equivalent lengths: extended-plenum fittings.

Figure 71-4 Equivalent lengths of boot fittings.

Figure 71-3 Equivalent length of round supply system fittings.

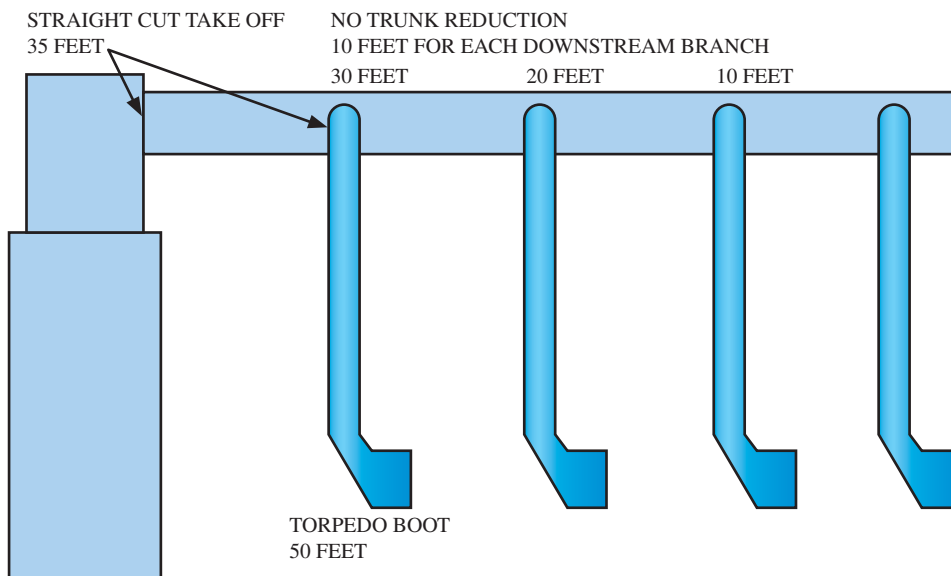

Figure 71-5 Example of branch duct total equivalent length using inefficient fittings.

branch, 15 ft for the distance from the blower to the takeoff, and 20 ft for the distance from the takeoff to the boot, the total equivalent length is $30 + 15 + 20 + 120 = 185$ ft.

This can be improved by using more efficient duct fittings. The trunk leaving the plenum can be reduced to 10 ft by using a tapered fitting. Similarly, the branch takeoff can be reduced to 15 ft. The downstream branch factor has been eliminated by using a reducing trunk. Replacing the 90° boot with an elbow and straight boot changes the equivalent length of the boot from 50 ft to 15 ft. All of these changes together reduce the equivalent length of fittings to 40 ft, making the total equivalent length $15 + 20 + 40 = 75$ ft (Figure 71-6). Often, the added cost of using more efficient fittings is offset by being able to use a smaller duct at a higher friction rate.

The bottom line is that many duct runs exceed 100 equivalent feet. The design friction rate will have

to be adjusted lower to keep the actual pressure drop through the run from exceeding the desired pressure loss through the run. This is done using the formula shown in section 71.4 or the length conversion scale on the ACCA duct calculator.

71.4 USING A DUCT FRICTION LOSS CHART

Duct friction loss charts are used to design duct systems. Figures 71-7 through 71-10 show the standard scales:

- Air volume, vertical lines shown in red (Figure 71-7)
- Static pressure loss (friction loss), horizontal lines shown in blue (Figure 71-8)
- Duct size, diagonal lines shown in green (Figure 71-9)
- Air velocity, diagonal lines shown in yellow (Figure 71-10)

Figure 71-6 Example of branch duct total equivalent length using efficient fittings.

Figure 71-7 The air volume lines are highlighted in red on this duct friction chart. (2009 ASHRAE Handbook—Fundamentals. © ASHRAE., www.ashrae.org.)

Figure 71-8 The friction loss lines are highlighted in blue on this duct friction chart. (2009 ASHRAE Handbook—Fundamentals. © ASHRAE., www.ashrae.org.)

If any two values are known, all the other values can be determined from the chart. For example, 1,000 CFM moving through a 12-in duct will have a velocity of approximately 1,300 fpm and the rate of static loss will be just under 0.2 in wc per 100 equivalent feet of duct (point A on Figure 71-11). Most commonly, the design friction rate and airflow volume are the two known quantities. To select a duct size for a specific friction rate, find the intersection of the air volume and friction rate lines. Moving 1,000 CFM at a friction rate of 0.1 in wc per 100 ft of duct will require a 14-in duct (point B on Figure 71-11).

It is important to recognize the difference between rate and absolute value. The friction rate chart does not tell the

designer what the actual loss through a duct will be because that depends upon the duct length. Rather, it tells the designer what the loss will be for every 100 ft of duct length. To determine the actual static pressure loss for a given CFM with any length run

$$\text{Actual static loss} = (\text{total equivalent length}/100) \times \text{friction rate per 100 ft}$$

A 50-ft section of duct would be half as long as a 100-ft duct and would create only half the static pressure drop. Since a 100-ft length of 6-in duct loses 0.085 in wc static pressure while moving 100 CFM, it will lose half of that, 0.0425 in wc, to move 100 CFM through a 50-ft section.

Figure 71-9 The duct size lines are highlighted in green on this duct friction chart. (2009 ASHRAE Handbook—Fundamentals. © ASHRAE, www.ashrae.org.)

Figure 71-10 The air velocity lines are highlighted in yellow on this duct friction chart. (2009 ASHRAE Handbook—Fundamentals. © ASHRAE, www.ashrae.org.)

A 200-ft section of 6-in duct would lose twice the static pressure, 0.17 in wc, while moving 100 CFM. Since all duct runs are not the same length, they will not all deliver the same amount of air, even if they are all the same size duct. This is why it is inaccurate to state that a 6-in duct will carry 100 CFM at a static pressure of 0.085 in without any reference to its length.

Most of the time the available static pressure is known and what the designer is looking for is what size duct will deliver the correct amount of air. In this case, the friction rate is adjusted so that the end result is equal to the design static pressure. The friction rate can be

adjusted for different lengths of duct using the following formula:

$$\text{Adjusted friction rate} = \text{design friction rate} \times (100/\text{equivalent length})$$

For example, the adjusted friction rate using a system design friction rate of 0.10 in wc and a duct length of 50 ft would be $0.1 \text{ in wc} \times (100/50) = 0.2 \text{ in wc}$. At 0.2 in wc, the air will lose exactly 0.1 in wc static pressure traveling 50 ft. The adjusted friction rate for a 200-ft run would be $0.1 \text{ in wc} \times (100/200) = 0.05 \text{ in wc}$. At 0.05 in wc, the air will lose exactly 0.1 in wc by the time it travels 200 ft.

Figure 71-11 Friction chart examples. (2009 ASHRAE Handbook—Fundamentals. © ASHRAE., www.ashrae.org.)

71.5 USING A DUCT CALCULATOR

Duct calculators are the most commonly used duct design tools. They take the place of friction charts and moderately complex calculations. All duct calculators have a few standard scales: round duct size, square-to-round conversion, friction rate per 100 ft, velocity, and volume. Lining up any two of these variables will allow you to look up the others. Most duct calculators are designed for smooth galvanized metal duct. Some of these will give conversion factors to accurately calculate other types of duct. The ACCA duct calculator offers a number of advantages over most other duct calculators. It gives friction rates for many different types of duct, converts velocity pressures to velocity, and has a convenient scale for determining the actual static pressure loss of a duct whose equivalent length is not 100 ft (Figure 71-12).

Sample Calculations

Place the arrow on “6” in the round duct diameter window. Find 100 in the volume window. Directly across from 100 CFM in the galvanized metal friction rate window you should see approximately 0.085 in wc (Figure 71-13). In the flexible duct friction rate window you should see approximately 0.15 in wc (Figure 71-14). These numbers represent

Figure 71-12 ACCA duct calculator. (© Air Conditioning Contractors of America, Arlington, VA ACCA.org)

Figure 71-13 A 6-in metal duct carrying 100 CFM has a static pressure loss of 0.085 in wc per 100 ft. (© Air Conditioning Contractors of America, Arlington, VA ACCA.org)

Figure 71-14 A 6-in flex duct carrying 100 CFM has a static pressure loss of 0.15 in wc per 100 ft. (© Air Conditioning Contractors of America, Arlington, VA ACCA.org)

the static loss per 100 ft of duct when 100 CFM is traveling through it. Now with the arrow in the round duct size window still pointing to "6," find 100 CFM in the volume window opposite the velocity window. Directly across from 100 CFM, you should read approximately 520 fpm (Figure 71-15). This is the velocity of 100 CFM of air traveling through a 6-in duct.

Of course, any two known values can be used to look up the others. To design for a particular static pressure, line up the static pressure across from the CFM and then look at the duct size to determine what size duct is needed. Another use is to design the system to maintain a particular duct velocity. The required duct size can be determined by lining up the design velocity across from the needed CFM.

Figure 71-15 100 CFM of air traveling through a 6-in duct has a velocity of approximately 520 fpm. (© Air Conditioning Contractors of America, Arlington, VA ACCA.org)

Figure 71-16 At a friction rate of 0.85 in wc, a 50-ft length of duct will lose 0.042 in wc; a 200-ft length will lose 0.17 in wc. (© Air Conditioning Contractors of America, Arlington, VA ACCA.org)

The ACCA duct calculator has a handy conversion chart at the bottom on the side that says "Auxiliary Calculations." Using the earlier example of 100 CFM at 0.085 in wc, put the 100-ft arrow across from 0.085 in wc. Now look across from the 50-ft mark and see an adjusted static of 0.042 in wc. Without moving the duct calculator, look across from 200 ft and you should see 0.17 in wc (Figure 71-16). This scale can also be used to determine what design friction rate is needed to achieve a desired design static pressure drop for a duct run that is not 100 ft long.

Suppose a system is to be designed with a supply duct static loss of 0.085 in wc. What friction rate would achieve 0.085 in wc pressure drop in a 50-ft duct? Note that in this case the end result is 0.085 in wc, not the rate per 100 ft. Line up the 0.085 in wc with 50 ft. Now look across from the arrow at 100 ft and you should see approximately 0.17 in wc (Figure 71-17). A 50-ft duct with a friction rate of 0.17 in wc will give exactly 0.085 in wc drop. Looking in the round duct diameter window you should see that a 5-in duct will handle 100 CFM at this friction rate (Figure 71-18). Now line up 0.085 in wc with the 200-ft mark. The arrow at the 100-ft mark indicates that we should use 0.042 in wc to design a 200-ft duct

Figure 71-17 For a 50-ft section of duct to lose 0.085 in wc, the friction rate should be 0.17 in wc. (© Air Conditioning Contractors of America, Arlington, VA ACCA.org)

Figure 71-18 A 5-in duct can handle 100 CFM at a friction rate of 0.17 in wc. (© Air Conditioning Contractors of America, Arlington, VA ACCA.org)

(Figure 71-19). Line up 0.042 in wc with 100 CFM and look in the round duct size window. You should see that a 7-in duct is required for this 200-ft duct (Figure 71-20). Notice that the 50-ft 5-in duct, the 100-ft 6-in duct, and the 200-ft 7-in duct will all deliver the same amount of air with a static pressure loss of 0.085 in.

To design a truly balanced system, the design friction rate for each run should be adjusted. This scale comes in very handy when designing duct systems.

Figure 71-19 For a 200-ft section of duct to lose 0.085 in wc, the friction rate should be 0.042 in wc. (© Air Conditioning Contractors of America, Arlington, VA ACCA.org)

Figure 71-20 A 7-in duct can handle 100 CFM at a friction rate of 0.042 in wc. (© Air Conditioning Contractors of America, Arlington, VA ACCA.org)

71.6 DUCT DESIGN GOALS

There are three basic goals when designing a duct system. In order of importance, they are as follows:

1. Allow the system to circulate enough air to operate properly.
2. Distribute the air proportionally to where the heat load is.
3. Keep airflow noise below objectionable levels.

Minimum Duct Restriction

The first goal is the most important. All heating and cooling equipment that circulates air has some minimum requirement for airflow. A duct system that will not allow the unit to deliver this minimum airflow will cause inefficient operation at best and equipment problems at worst. A fan's capacity is stated as the amount of air it can move against a particular pressure. This pressure is usually stated in inches of water column (in wc). Friction charts and/or duct calculators help determine the amount of static pressure drop a particular type and size of duct will offer to any given airflow. In general, as more air is pushed through the same size duct, the pressure drop through the duct increases. Duct calculators or friction charts show the amount of resistance a duct has to airflow. This is stated as static pressure loss per 100 ft of duct, measured in inches of water column. It is important to keep in mind that this is a friction rate, not an absolute quantity. In other words, a duct length is necessary to accurately determine what the static loss will be for a particular duct.

Required Information

To design a duct system that will allow the fan to move an adequate amount of air, the designer needs to know the following:

- **System CFM** The amount of air the system must move
- **Maximum available system static** The maximum static pressure available for moving that quantity of air
- **Duct friction rate** The airflow resistance of the duct material has to airflow

System Airflow

Airflow is measured in cubic feet per minute, or CFM. As the term suggests, CFM measures the volume of air that is moved every minute. Systems can operate correctly over a range of airflows. The proper airflow requirement is found in the manufacturer’s design and specification literature. If you do not have a specification sheet to work from, 400 CFM per ton of cooling works for most residential equipment. The ductwork should be designed to handle the higher of the heating or cooling system airflow. The cooling airflow is usually used because the required airflow for cooling exceeds the required airflow for heating in most situations. Cool air is heavier and therefore harder to move.

In air conditioning, the airflow across the evaporator helps determine the amount of sensible cooling versus the amount of latent cooling accomplished. Reducing the airflow will increase the amount of moisture removed from the air but decrease the amount of sensible cooling accomplished. Conversely, increasing the airflow reduces the latent cooling but increases the sensible cooling. The amount of sensible and latent cooling required can be determined by using ACCA Manual J. It is important to recognize that duct sizing is done on the basis of sensible cooling capacity, not total cooling capacity. Sensible capacity is what is going to actually cool the room down, so the sensible heat load for each room is used to determine how much air that room requires.

Maximum Available System Static

The maximum static pressure the equipment can operate against is usually specified by the equipment manufacturer. Keep in mind that anything the air must travel over or through will create some static pressure drop. Examples of devices that produce a static pressure drop include evaporator coils, humidifiers, air filters, grilles, and registers. The amount of static pressure loss for any of these devices depends upon the airflow rate. More airflow creates a higher static pressure loss. The maximum available static pressure for the duct system can be determined by subtracting all losses except ductwork from the maximum operating static pressure of the equipment at the design airflow.

For example, take a 2-ton system moving 800 CFM of air with a total available static pressure of 0.55 in wc, an evaporator coil with a static pressure drop of 0.25 in wc, a filter with a static pressure drop of 0.10 in wc, and supply registers and return grilles with a static pressure drop of 0.05 in wc. All the fixed losses add up to 0.4 in wc, leaving 0.15 in wc of pressure for ductwork.

Limiting Air Noise

The design static pressure that has been determined is for the entire duct system. If the supply duct is designed at 0.15 in wc and the return duct at 0.15 in wc, the total duct static loss would be 0.3 in wc and the fan will not move enough air. The supply static and return static added together needs to equal 0.15 in wc.

One determining factor for design static for the supply and return ducts should be the velocity of the air as it travels through the duct. It is possible to select a duct size that will maintain a workable static pressure but end up with a velocity that creates an objectionable amount of noise. If air moves faster than 600 fpm it begins to make noise. Above 1,000 fpm, the customer will have to turn up the television when the air conditioning starts.

In general, as duct sizes increase, design static must decrease to maintain the same velocity. There are normally more supply registers than return-air grilles in most systems. This means that the return-air ducts must handle more air than the supply ducts. Therefore, return-air ducts are larger than supply-air ducts. If return-air ducts are sized exactly like supply-air ducts, the return-air ducts will often be noisy. Figure 71-21 shows the maximum design static for several sizes of duct at velocities of 600 fpm and 1,000 fpm.

A quick look at Figure 71-21 shows that if a designer sticks strictly to a 600 fpm maximum velocity, the main supply trunk ducts and all the return ductwork will be rather large. Any duct that ends in a supply register or a return grille should be limited to a 600 fpm velocity. However, the trunk ducts that supply the branch ducts can operate at higher velocity and noise levels because they do not open up into the living area. Still, 1,000 fpm is considered the outer limit for velocity in trunk ducts in residential systems.

71.7 DETERMINING BRANCH DUCT AIRFLOW

To have an even temperature throughout the house, the amount of air each room receives should be based on the heat load for each room. Typically, the airflow required for both heating and cooling is calculated and the higher value chosen.

Dividing the entire building heat load by the system CFM will tell how much BTU/hr is delivered for every CFM of airflow. For example, a house with a heating load of 30,000 BTU/hr and an airflow of 600 CFM would have a heating airflow divisor of 30,000/600 = 50 BTU/CFM. If a room in

Figure 71-21 Airflow through metal duct at 600 fpm and 1,000 fpm velocities.

@600 fpm Duct Velocity			@1000 fpm Duct Velocity		
Duct Size	Friction Rate (in wc)	CFM	Duct Size	Friction Rate (in wc)	CFM
6	0.11 (in wc)	120	6	0.3 (in wc)	290
8	0.085 (in wc)	220	8	0.2 (in wc)	350
10	0.07 (in wc)	330	10	0.15 (in wc)	550
12	0.055 (in wc)	480	12	0.12 (in wc)	780
14	0.045 (in wc)	650	14	0.10 (in wc)	1,050

this house had a heating load of 4,000 BTU/hr, the required airflow for heating that room would be $4,000/50 = 80$ CFM.

To determine the cooling airflow divisor, divide the total calculated sensible cooling load by the amount of airflow the system will move to arrive at a capacity divisor. For example, a house with a sensible cooling load of 16,000 BTU/hr and an airflow of 800 CFM would have a capacity divisor of $16,000/800 = 20$ BTU/CFM. If a room in this house had a sensible cooling load of 2,400 BTU/hr, the required airflow for cooling that room would be $2,400/20 = 120$ CFM.

TECH TIP

Airflow divisors are simply reciprocals of airflow factors, as used in ACCA Manual J. Using the example of 30,000 BTU and 600 CFM, the airflow factor would be calculated by dividing 600 CFM by 30,000 BTU/hr to get 0.02 CFM per BTU/hr. This number is then multiplied by the room load to get the required airflow. For example, $0.02 \times 4,000 \text{ BTU/hr} = 80 \text{ CFM}$. By contrast, the airflow divisor has the advantage of being a "normal" number, rather than a tiny decimal number. This reduces rounding error and keeps the process simpler. The air flow divisor is 50 for the same system. So the same calculation is $4,000 \text{ BTU/hr} / 50 = 80 \text{ CFM}$.

71.8 BRANCH DUCT SIZING

Three pieces of information are required to size each branch duct: the system design static pressure, the total equivalent length of each run, and the required airflow for each run. A friction chart or duct calculator can be used to determine what size duct will be required to deliver the correct amount of air at the design static. Line up the duct's total equivalent length, including fittings, with the adjusted design static on the scale for duct length adjustments. Now look at the static pressure indicated by the arrow at the 100-ft mark. This is the value that will be used to look up the duct size on the other side of the duct calculator. On the other side of the duct calculator, line up this adjusted static with the required CFM for the duct run. The arrow in the round duct window will indicate the size of round duct that will deliver the required amount of air at the design pressure loss for that duct run.

You have many of the same issues on the return side. Ideally, each return should handle the air from the supply registers in the portion of the house where the return is located. It is critical that the total amount of air handled by all the returns adds up to the total system CFM. It is also important that air be able to move from one room to another easily. Air will not enter a room if the air that is already in the room cannot leave.

SERVICE TIP

Undersized returns are a common problem found in duct systems today. A marginal duct system can often be dramatically improved by adding additional return-air runs.

Airflow (CFM)	Adjusted Design Static (in wc)
120	0.12
80	0.08
100	0.10
200	0.11

Figure 71-22 Trunk duct sizing example data.

71.9 TRUNK DUCT SIZING

Each trunk duct should be able to carry the total volume of air for all its connected branches at the static pressure loss of the branch with the lowest adjusted static. For example, a trunk duct to supply the four branch ducts listed in Figure 71-22 would be sized for 400 CFM at a design static of 0.08 in wc.

The trunk duct is sized using a friction chart or duct calculator. In this example, a 10-in-diameter duct would be the closest actual duct size (Figure 71-23).

71.10 GRILLE AND REGISTER SELECTION

Supply-air registers or diffusers are responsible for distributing the air into the room. Without the correct diffuser, the room can still be uncomfortable even if the system and ductwork are sized correctly. The overall goal is to ensure even temperature throughout the room without creating noise and drafts. In general, the supply air should not blow directly on the people in the room. The primary factors to be considered when selecting supply-air registers are the following:

- Required CFM
- Throw

Figure 71-23 Duct selection for 400 CFM at 0.085 in wc. (© Air Conditioning Contractors of America, Arlington, VA ACCA.org)

Table 71-1 Terminal Velocity for Common Residential Diffusers

Register Type and Location	Terminal Velocity (fpm)
Floor register	50
Sidewall register	75
Round ceiling diffuser	50
Square ceiling register	75–150

- Face velocity
- Static pressure drop

Required CFM

The required air volume is measured in cubic feet per minute, or CFM. The CFM for the branch duct is determined based on the heat load for the area the register serves. The register must be designed to handle this quantity of air.

Throw

The throw is important because it determines how far into the room the conditioned air travels. The register throw is the distance from the register that the air will travel before it slows down to the terminal velocity listed in the engineering data. Table 71-1 shows the terminal velocity for common residential diffusers.

The desired throw is also determined by register location. Floor registers should have a throw of at least 6 ft to get the air up to head height. This is especially true for cooling applications with floor registers. If the throw is too little, the cold air will stay near the floor. However, the throw should be less than the ceiling height. Using a floor register with a 10-ft throw in a room with an 8-ft-high ceiling will create drafts as the air bounces off the ceiling.

For high-sidewall registers, the throw should be equal to 75–100 percent of the distance from the register to the opposite wall. Again, this is primarily a concern in cooling. Too small a throw will cause dumping, where the cold air falls to the floor. This causes drafts where the air is falling. Excessive throws cause bouncing off the wall and also produce drafts.

Large throws should be avoided with low-sidewall registers because the air blows into the occupied zone. Low velocities and small throws will work with low sidewalls in heating only. Low-sidewall registers should not be used for air conditioning because it is impossible for them to get the air up at head height without blowing air into the area where people are.

Round ceiling diffusers should be located near the center of the room. The throw should be approximately equal to the distance from the register to the walls. Throws exceeding this distance can usually be tolerated because the air tends to roll down the walls. Too small a throw will cause dumping and drafts in air conditioning. In heating, short throws will cause the warm air to remain high up around the ceiling.

Face Velocity

The velocity of the air at the face of the register determines the throw and the noise. Higher velocities give larger throws

Table 71-2 Recommended Register Face Velocities

Type of Location	Recommended Face Velocity (fpm)
Broadcasting studios	500
Residences	500–750
Apartments	500–750
Churches	500–750
Hotel bedrooms	500–750
Theaters (live)	500–1,000
Private offices, acoustically treated	500–1,000
Motion picture theaters	1,000–1,250
Private offices, not treated	1,000–1,250
General offices	1,250–1,500
Retail stores	1,500
Industrial buildings	1,500–2,000

and also more noise. Lower velocities yield less noise and shorter throws. The main limitation of register face velocity is the noise created by the moving air. Table 71-2 shows recommended maximum face velocities for several different applications. Note that the quieter applications have lower recommended face velocities.

Static Pressure Drop

Since supply registers and grilles add restriction to the free flow of air out of the ductwork, air pressure is required to force the air through them. This is referred to as the static pressure drop across the register. Ideally, it should be kept as low as is possible, but it must be accounted for when designing a duct system. The registers selected should have a static pressure drop at the design airflow that is equal to or less than the assumed register pressure drop used to design the duct system. Like the noise, the pressure drop increases as the velocity increases. Most residential registers have a static pressure drop between 0.03 and 0.05 in wc when the face velocity is between 500 and 750 fpm.

Noise Criteria

The industry uses a noise criteria (NC) system to designate the level of noise in the area where the registers will be used. Each NC curve is assigned a number, in 5-dB increments. The number corresponds to the decibel reading at approximately 1,500 Hz. NC 25 is characteristic of areas with very little background noise, and NC 50 is characteristic of areas with so much background noise that people must be within a few feet of each other to talk. Most register manufacturers now include NC recommendations in their commercial register selection guides (Figure 71-24).

Engineering Data

The tables with the information on register performance are in the engineering data section of the manufacturer's

NC Rating	Application
NC-20	Concert halls, recording studios, large auditoriums, recital halls
NC 20 to NC 30	Small auditoriums, theaters, music practice rooms, court rooms
NC 25 to NC 35	Bedrooms, sleeping quarters, hospitals, apartments, hotels and motels
NC 30 to NC 35	Private offices, small conference rooms, classrooms, libraries
NC 35 to NC 40	Large offices, reception areas, retail shops, restaurants, gymnasiums
NC 40 to NC 45	Lobbies, maintenance shops
NC 45 to NC 55	Kitchens, laundry facilities and computer equipment rooms

Figure 71-24 Register selection table with integrated noise criteria information.

literature. Figure 71-25 shows the engineering data for a series of residential floor registers. The register face velocities are listed across the top with the static pressure loss across the registers listed immediately underneath the velocities. The register sizes are on the left-hand side with the effective face area of the register listed under each size. In

each box in the table are listed the CFM and throw for that size and face velocity. The easiest way to locate an acceptable register is to start with one criterion and look for the rest. This can be demonstrated by an example.

Suppose a register is needed for an air volume of 100 CFM, a throw of 6 to 8 ft, a pressure drop of no more than 0.03 in wc, and a face velocity below 700 fpm. Under the 700 fpm velocity column, note that a 4 x 10 will handle 120 CFM at the maximum acceptable velocity. Move to the left to find 100 CFM listed under the 600 fpm velocity column. This selection matches our volume, velocity, pressure drop, and throw requirements. There are many register sizes that can handle 100 CFM, but only a few that will meet all our requirements. For example, a 6 x 12 will handle 100 CFM but with a throw of only 4 ft.

Return-Air Grilles

Return-air grilles primarily serve to hide what would otherwise be a large unsightly hole. They do not direct the air like supply registers do. A generally accepted rule for estimating the required return-air grille size is that it should have 1 in² of gross area for every 2 CFM of air it handles. However, manufacturers' selection charts are the most accurate way to size return grilles. The selection criteria for return-air grilles are as follows:

- Air volume
- Pressure drop
- Face velocity

Typical Floor Register Performance Data

Figure 71-26 Return-air grille selection chart.

Ideally, the pressure drop should be kept as low as is possible, but it must be accounted for when designing a duct system. The grille's static pressure drop at the design airflow should be equal to or less than the assumed pressure drop used to design the duct system. Just as in sizing supply registers, the pressure drop and noise both increase as the velocity increases. The face velocity should be kept under 600 fpm; faster velocities lead to noticeably increased air noise.

Figure 71-26 shows a typical return-air grille selection chart. The face velocities are listed across the top. The grille sizes are on the left-hand side with the effective face area of the grille listed under each size. In each box in the table are listed the CFM and static pressure drop for that size and face velocity. Suppose a return grille was needed to handle 400 CFM with a face velocity of less than 600 fpm and a static pressure drop of 0.03 in wc or less. Under the 600 fpm column, a 8 × 14 will handle 410 CFM, with a pressure drop of 0.019. Other sizes also meet our criteria: a 10 × 12 has a pressure drop of 0.019 in wc with a volume of 430 CFM.

Filter Grilles

Filter grilles should be sized larger than standard return-air grilles because the filter reduces the effective area of the grille and because a lower velocity across the filter is needed for it to be effective. Maximum face velocities of 300–400 fpm are recommended.

UNIT 71—SUMMARY

Duct systems distribute conditioned air through a building. The basic components are a blower, supply-air ducts, and return-air ducts. Duct systems are designed using load calculations, equipment performance specifications, and building plans.

All components in the airstream create static pressure loss, including the air filter, evaporator coil, electric heaters, humidifiers, supply registers, and return-air grilles. The static pressure available for moving air through the duct system is found by subtracting all losses other than duct losses from the blower total external static pressure at design airflow. The pressure lost as air travels through duct fittings is measured in equivalent feet of pipe. The total equivalent length of a duct run is found by adding the length of the trunk duct, branch duct, and the equivalent length of all the fittings. Duct is sized using a friction chart or duct calculator. Friction charts and duct calculators give the friction rate per 100 ft of duct. The actual pressure drop through any duct will also depend upon its total equivalent length.

UNIT 71—REVIEW QUESTIONS

1. What friction rate should be used to size a duct for a static pressure drop of 0.1 in wc if the duct has a total equivalent length of 150 ft?

2. What size metal duct should be used to deliver 170 CFM with a pressure drop of 0.15 in wc if the total equivalent length is 130 ft?
3. What friction rate should be used to size a duct for a static pressure drop of 0.1 in wc if the duct has a total equivalent length of 50 ft?
4. What size metal duct should be used to deliver 290 CFM with a pressure drop of 0.15 in wc if the total equivalent length is 80 ft?
5. What is the velocity of 500 CFM of air moving through a 10-in duct?
6. Why should all ductwork designs start with an accurate heat load study?
7. What is the total available static pressure for the ductwork for a system with the following specifications?
Blower: 0.55 in wc total external static at design airflow
Evaporator coil: 0.25 in wc static pressure drop at design airflow
Filter: 0.1 in wc static pressure drop at design airflow
Registers and grilles: 0.05 in wc static pressure drop at design airflow
8. Why should air velocity in branch ducts be limited to 600 fpm?
9. Why are duct friction charts designed for sheet-metal ducts not accurate for fiberglass ductboard or flexible ducts?
10. Why do fiberglass ductboard and flex duct have higher friction loss rates than sheet metal?
11. What is the purpose of reducing the trunk duct size in a reducing extended-plenum duct system?
12. What is the maximum static pressure difference that most residential blowers are designed for?
13. What is the recommended face velocity for a return-air filter grille?
14. Explain what manufacturers mean by a register's throw.
15. List the factors to consider when choosing a supply register.
16. What are the noise criteria curves?
17. Using Figure 71-25, select a floor register that will provide an 8–10 ft throw for 150 CFM with a face velocity less than 700 fpm.

UNIT 72

Zone Control Systems

OBJECTIVES

After completing this unit, you will be able to:

1. explain the purpose of zone control systems.
2. list the methods used to control excess airflow in a zone system.
3. explain the purpose of variable air volume control systems.
4. describe the operation of a basic zone control system.
5. list the components commonly used in a zone control system.
6. explain the difference between a basic zone control system and a communicating zone control system.

72.1 INTRODUCTION

Zone control gives customers increased control over their comfort systems. Customers are no longer satisfied with systems that leave one part of their house hot while another part is cold. Zone systems allow control over different portions of the house without installing multiple units.

Many heating and air-conditioning installations are installed in buildings where the floor plan is spread out, such as ranch-style and split-level houses. On these jobs it is not practical to control comfort throughout the entire area using one thermostat. These layouts require zoning, because the loads differ from one area to another. For example, a basement area typically needs a significant amount of heat to stay warm in the winter but needs virtually no cooling in the summer. The amount of air delivered to the basement needs to change between seasons. Zoning solves this problem.

72.2 PRINCIPLES OF ZONING

Zoning is a method of controlling the supply of conditioned air to each unique area to match the load requirements. This is done by separating the air supply to each unique area by the use of a zone damper in the ductwork and controlling each zone damper with an individual thermostat.

The first consideration when selecting a zoning system is to determine what areas of the building are to be zoned. This can range from a two-zone system for a two-level house to a system that handles each room as a separate zone. Areas to be zoned are selected by building use, building load, or building orientation.

Building-use zoning is based on separating the areas depending on how they are used. For example, bedrooms can be on one zone and living areas on another. This is common for residential zoning.

operation of zoned systems. Occupancy sensors will allow a zone to be activated only when it is occupied. The popularity of occupancy sensors has resulted in a decrease in their cost so that they now can be used for many more applications. In fact, occupancy sensors have already found their way into residences for light switches.

Building load and orientation zoning considers the areas of a building with unique heat loads. For example, the south side of a building would be on a separate zone from the north side. This type of zoning is common for commercial structures.

The following are some examples of zone controlled systems:

1. A three-zone split-level system is shown in Figure 72-1. Each level of this residence has a separate trunk duct from the supply-air plenum with a zone damper installed. Each of these dampers is controlled from an individual thermostat located in that zone.
2. Zone control for a bilevel house is shown in Figure 72-2. This system has three zones: living area, bedrooms, and recreation room. The system uses a zone control panel, a 40 VA transformer, three zone dampers, and three thermostats.
3. A room-by-room temperature control is shown in Figure 72-3 for a five-zone radial system. These ducts can be located overhead or in the slab floor.

Figure 72-1 Three-zone split-level system.

TECH TIP

Occupancy sensors, devices that detect movement of people in an area, can be used to enhance the efficient

Figure 72-2 Zone control for a bilevel house.

Figure 72-5 Four-zone professional office system.

Figure 72-3 Five-zone radial system.

SERVICE TIP

Some homeowners will close off the vent to rooms that are not in use or commonly used, such as spare bedrooms. If enough of the system's capacity is shut down as a result of this attempt to economize, it can actually cause major problems with the system itself. For example, reducing the airflow below the manufacturer's specifications can reduce the heat load on the evaporator. This can cause refrigerant floodback to the compressor, shortening its life. Another example is raising the discharge-air temperature of a gas furnace by restricting the airflow through it. This causes the high limit to cycle the furnace off and on, reducing its efficiency. An attempt to economize in this manner may ultimately result in higher utility bills and shorter equipment life for the owner.

4. A two-zone ranch house is shown in Figure 72-4. Each zone has a thermostat controlling a zone damper.
5. A four-zone office building system is shown in Figure 72-5 using a zone control panel, four dampers and thermostats, and a 40 VA transformer.
6. A room-by-room comfort control layout is shown in Figure 72-6. In this illustration each outlet has an automatic square-to-round transition damper.

Figure 72-4 Two-zone ranch-style house.

Figure 72-6 Individual room zone control system.

72.3 RELIEVING EXCESS AIR PRESSURE

A problem that can occur on a system of thermostatically controlled zone dampers is forcing too much air through the portions of the duct system that remain open. When some major zone dampers are closed off, the remaining zones must handle an excessive amount of air. This can cause reduced overall system airflow, air noise, drafts, and poor control in the operating zones. The solution to this condition is to provide some means of relieving this excessive air pressure.

There are a number of ways to accomplish this, including the following:

- Bypassing supply air to the return
- Dumping excess air into an area whose temperature is not critical
- Using dampers that allow some air to pass even when they are closed
- Oversizing the ductwork so that a single zone can handle the system airflow
- Variable air volume

Air Bypass Method

The most commonly used method is to bypass supply air back into the return-air duct as shown in Figure 72-7. This is usually accomplished by adding a barometric damper between the supply and return. When the pressure differential exceeds the setpoint of the damper, it opens to relieve the pressure. This ensures that the static pressure across the blower never exceeds the setpoint of the bypass damper.

Figure 72-7 Relieving air pressure through bypassing air from the supply plenum back to the return.

Keeping the system pressures and velocities under control eliminates air noise and objectionable drafts.

The disadvantage of this arrangement is that it does nothing to solve the problem of system load. The system is operating with only a partial load. With prolonged use on heating, the high limit control may shut down the system. In cooling, the evaporator can freeze from lack of load. Plenum thermostats are used to address this problem.

A plenum, or discharge air thermostat, is frequently used to shut off the heating system when the discharge air starts to get too hot. Similarly, a low limit is used to shut down the compressor when the discharge air starts to get too cold. On systems that use thermistor sensors, a single discharge air sensor is used. The discharge thermostat solves the problem of equipment capacity exceeding the load, but it creates a new problem: short-cycling. The discharge-air temperature can change rapidly when only a single zone is open, causing the system to shut off before the demand in that zone is met. The system will come back on as soon as the required off time is satisfied. Thus, the system can short-cycle trying to meet the demand of a zone whose load is much smaller than the system capacity.

Dump Zone

The pressure difference can be relieved by dumping excess air into a zone whose temperature is not critical, as shown in Figures 72-8 and 72-9. Again, a barometric damper can be used to accomplish this. If the dump zone is large enough, discharge air thermostats are usually not required. This solves both the air velocity problem and the system load problem but can create a problem with the comfort in the dump zone. Using a dump zone can also have an impact on energy cost because the system is over-conditioning an area that might not be conditioned at all if it were not a dump zone.

Figure 72-8 Duct arrangement for a "dump" zone.

Figure 72-9 Relieving air pressure by dumping it into the basement.

Damper Leakage Method

The damper leakage method essentially uses the entire building as a dump zone. Some air passes by all the dampers, but more is directed through the open damper. This system is simple; it does not involve any bypass dampers or discharge air thermostats.

This can be accomplished by adjusting standard dampers to still be slightly open in the closed position or using dampers that are slightly smaller than the duct they are in. Using this method, a small amount of air will be supplied all the time; even to the zones that are not calling.

The system performance of a damper leaking system is difficult to predict. If the loads in the zones are not close to the same, the system will not maintain the correct temperature in any zone except the zone with the highest load.

Oversized Duct

Another approach is to size each zone duct to handle 60–70 percent of the total system air volume. This keeps the equipment operating correctly and puts the air where the load is. It can create problems with the air distribution in the rooms. As the volume of air leaving the registers changes, so does the throw. If the registers are sized for the largest volume of air that will be moving through them, the throw will be too little when all the zones are open. On the other hand, if the registers are sized for a smaller amount of air, the registers will be noisy and drafty when the full system air volume is going to just one zone. This arrangement is really only practical on small jobs with two or three zones.

Variable Air Volume

A variable-air-volume system changes the amount of air the fan delivers to match the zone requirements, eliminating the need for bypassing or dumping air. When applying variable-air-volume zone systems, heating and cooling systems with staging or modulating capacity are used so that the system capacity can match the load on the system. In the past, this type of control was only available for commercial systems. With the advent of ECM variable-speed motors, variable-capacity residential equipment, and communicating controls, these systems are now available for residential systems.

One example of a variable-air-volume residential system is the Carrier Infinity Zone controller used on a variable-capacity heat pump. The control system uses only four wires: two for power and two for communications. The blower communicates zone airflow characteristics back to the system controller. Thus, the controller knows what the airflow and resistance of each zone is.

72.4 AUTOMATIC RELIEF DAMPERS

During relief operations, it is important to maintain at least the minimum airflow through the air-handling unit; otherwise the coil performance will be unsatisfactory. The following formula can be used to determine the quantity of bypass air:

$$\begin{aligned} &\text{air handler (CFM)} - \text{smallest zone peak (CFM)} \\ &\quad - \text{leakage of all closed dampers (CFM)} \\ &\quad = \text{bypass airflow (CFM)} \end{aligned}$$

Automatic dampers are used when either bypassing or dumping is required to relieve excess air pressure. Two types of dampers are used for this: barometric dampers and motorized dampers.

Barometric Dampers

Barometric static-pressure-relief dampers (Figure 72-10) require no electrical connections. They are used on low-pressure systems with static pressures usually below 0.5 in wc. They are held closed with either an adjustable weight or by spring pressure. When the pressure difference across the damper exceeds the weight or spring pressure, the damper opens. The amount of opening is regulated by the amount of air to be relieved. The advantage of these dampers is that they are self-regulating and require no power or control signals. The disadvantages are that they must be adjusted for each installation to work correctly and they tend to leak a little all the time.

Motorized Dampers

Motorized static-pressure-relief dampers are electrically or electronically operated by a zone control in response to

Figure 72-10 Static-pressure-relief damper.

a signal from a remotely located duct pressurestat. These dampers have the advantage of closing tighter when bypass is not needed, and they generally do not require adjustment. They do require a more sophisticated control system and a static pressure sensor.

72.5 TYPES OF DAMPERS

There are many shapes, sizes, and styles of zone dampers designed to fit different requirements and applications. The flat piece of metal that opens or closes the airstream in a damper is called a blade. Dampers are often listed by the blade style used in the damper. Some different damper styles available are the following:

- Opposed-blade damper for rectangular ducts
- Parallel-blade damper for rectangular ducts
- Single-blade dampers for round duct
- Retrofit dampers

Opposed-Blade Dampers

Opposed-blade dampers use flat, rectangular blades that pivot in opposite directions to each other. They form a V shape when they are closed. Opposed-blade dampers are most often used in commercial systems. They are well suited for variable volume applications where the damper will be operated in a partially open position.

Parallel-Blade Dampers

Parallel-blade dampers use flat, rectangular blades that pivot together in parallel with each other (Figure 72-11). Parallel-blade dampers are often used in commercial systems for controlling the return air and outdoor air. They are also commonly used in residential applications for rectangular duct dampers.

Figure 72-11 Parallel-blade damper. (Courtesy of Greenheck Fan)

Figure 72-12 Single-blade damper.

Single-Blade Dampers

Single-blade dampers are common in residential applications with round duct. They consist of a single piece of metal that pivots in the middle (Figure 72-12). Single-blade dampers are mainly used in residential applications

Retrofit Dampers

Adding regular dampers to an existing system requires duct modification. The labor and cost involved can be a deterrent to adding a zone controls to an existing system. Retrofit dampers are single-blade dampers designed specifically to be inserted into an existing duct. They are added by making a slot in the side of the duct, inserting the damper blade into the duct, and mounting the damper to the outside of it. Figure 72-13 shows a retrofit damper.

72.6 DAMPER LOCATION

The type of dampers used is partly determined by the general design of the duct system. In new systems, the duct can be designed with a separate trunk duct for each major zone. These zones are then controlled by large dampers that control flow through the entire trunk duct.

Figure 72-13 Retrofit damper. (Courtesy of Jackson Systems, LLC)

Figure 72-14 Zone damper for rectangular duct.

Trunk Duct Dampers

Most zone systems control airflow in the trunk ducts. This has the advantage of minimizing damper cost since a single trunk damper controls the airflow to several branch ducts. This method also keeps air noise to a minimum by placing the dampers away from the point where the air enters the house. The disadvantage of trunk duct dampers is that multiple trunk lines are required. This is more of a concern for retrofit applications than for new construction. Figure 72-14 shows a damper used for a rectangular trunk duct, while Figure 72-15 shows a damper used for a round trunk duct.

Branch Duct Dampers

Another strategy is to put a damper in every branch duct. The advantage of this strategy is that multiple trunk ducts are not required. However, the system expense goes up

Figure 72-15 Zone damper for a round duct.

rapidly because of the cost of the extra dampers. The system does not need to have a zone for every room when using branch duct dampers; several dampers can be slaved together and controlled from one zone. This is usually preferable to having a zone for every room. It is hard to control the system operation correctly if the zone is too small compared to the overall system capacity. The dampers used for branch ducts are smaller versions of dampers used for trunk ducts as shown in Figure 72-14 and 72-15.

Register and Diffuser Dampers

The damper can be built into the supply registers and diffusers. The advantage of this method is that changing the registers is usually easier than changing the ductwork. The disadvantages are the cost of buying a diffuser damper for every diffuser in the house and the noise created by throttling the air right where it enters the room.

72.7 DAMPER CONTROL

The two methods of controlling zone dampers are two-position control or modulating control. Some dampers may be used with either type of system, while others are designed exclusively for either two-position control or modulating control.

The dampers in a two-position control system are either open or closed; there is no partial opening or closing. Two-position control is simpler but generally does not provide as even a temperature control as modulating control. Dampers designed for two-position control can be either motor driven in both directions or motor driven in one direction and returned in the other direction by a spring. The control system for a spring-return damper can be simpler because it is energized in only one direction. Dampers that are motor driven in both directions can usually be applied to both two-position and modulating systems, while spring-return dampers are only applicable to two-position systems. The motor on a spring-return damper is usually stronger because it must overcome the spring as well as operate the damper.

Modulating controls can open and close the dampers in increments, rather than completely opening or closing the zone dampers. This type of control requires dampers that are powered in both directions. The zone control system for a modulating damper system is usually more complex. Modulating zone damper control can be used in conjunction with air bypass to produce variable-air-volume control to a system without changing the fan speed.

SERVICE TIP

Zone dampers must be located as close as possible to the plenum or supply trunk. If they are too close to the register, there is a possibility that air passing a partially opened damper will cause a whistling sound that can be heard in the room. If a sound can be heard and it is possible to move the damper farther away, one method of eliminating the sound is to put one or more 90° turns in the duct after the damper and before the room register.

72.8 TYPES OF ZONING SYSTEMS

A number of manufacturers make control systems for installations requiring zoning. These systems differ in number of zones handled, types of applications, methods of control, and types of adjustments provided. The types of systems available generally fall into two categories: basic systems that stress simplicity and advanced systems that stress performance.

Basic Zone Control Systems

The most basic zone control systems are typically limited to a maximum of four zones, single-stage heating and cooling, and two-position damper control and require either bypassing or dumping to control the air pressure. These systems typically are designed to work with standard off-the-shelf thermostats. Wiring for these systems is usually letter for letter: R to R, G to G, and so on. The emphasis of these systems is simplicity. On many of these, one of the thermostats is considered the master, and the system selection is determined by its system setting. The system will cycle on by any of the thermostats, but only the master determines whether the system is in heating or cooling.

Added Features

Companies offering these basic types of zoning panels also offer systems with more features. Items like two-stage heating or cooling or dual-fuel heat pump integration can be included. These systems still use traditional 24 V thermostats, two-position dampers, and bypass air, but they do have the ability to work with more efficient staged heating and cooling equipment.

Advanced Zone Systems

Other zoning systems stress a high level of technology to achieve enhanced performance and comfort. Typically these systems take advantage of equipment with variable-speed ECM blower motors, modulating damper control, and staged-capacity heating and cooling. Normally, the controls are proprietary, not common over-the-counter controls. Temperature is typically measured using thermistor sensors.

72.9 BASIC ZONE CONTROL SYSTEM

Ultrazone EWC-ST-3E Zone Control Panel

Ultrazone EWC-ST-3E zone control (Figure 72-16) is an example of a basic zone control system. The system is designed to work with standard heating and air-conditioning equipment. Either mechanical or non-power-robbing electronic thermostats may be used. A single control is capable of controlling a two-zone or three-zone system. If a greater number of zones are required, controls may be interconnected for additional zones.

A thermostat and a damper are required for each zone. The zone dampers are controlled by the zone control panel and operate in two positions; dampers are either fully open or

Figure 72-16 Basic three-zone control panel.

fully closed. The zone thermostats send a signal to the zone control and the control operates their respective dampers.

The zone 1 thermostat determines whether the system is operating in heating, cooling, or is off. The zone 1 thermostat must have an O terminal that is energized in cooling and a B terminal that is energized in heating. These signals tell the zone control whether the system will operate in heating or cooling. There will be either six wires connecting the panel to the zone 1 thermostat, or seven wires if the thermostat requires a common terminal connection. All other zone thermostats can be simple three- or four-wire thermostats.

Since the EWC-ST-3E zone control panel is designed for limited applications, there is no programming and no mode switches. The panel has a single J1 jumper that determines fan operation in heat. With the jumper in place, the zone panel sends 24 V to the system's G terminal during heat. With the jumper cut, the panel does not send 24 V to the unit in heat, as in a gas furnace.

Control Panel Wiring

A wiring diagram for a typical zone control panel is shown in Figure 72-17. The system shown is for three zones. For more than three zones, a slave panel would be used. Note that there are seven wires between the panel and the zone 1 thermostat and only five wires to the other two-zone thermostats. All damper motors are wired with three wires. Also note that the panel requires a separate field-supplied 24 V, 40 VA transformer.

SERVICE TIP

A separate 24 V, 40 V A transformer is required for most zone panels. The transformer on the indoor unit should not be used to supply 24 V to the zone control panel. The additional load will overload the transformer, causing transformer failure and erratic system operation.

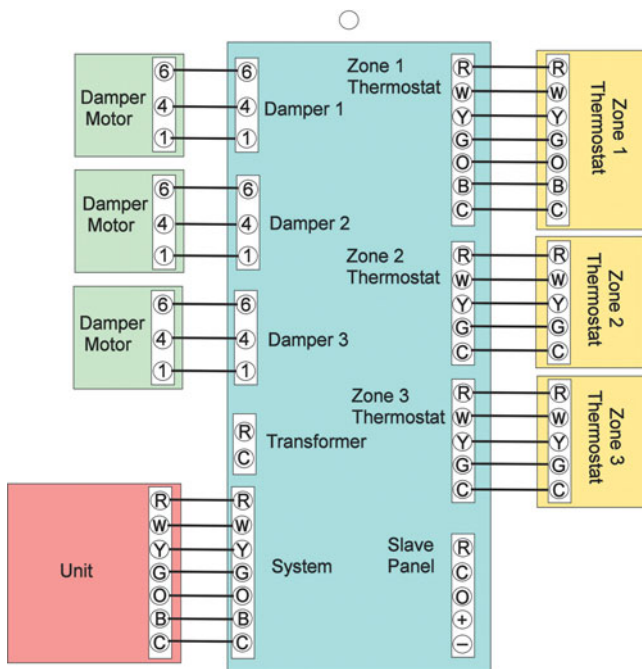

Figure 72-17 Typical wiring for basic relay based zone panel.

72.10 BASIC ZONE CONTROL SYSTEM OPERATION

System switching from heating to cooling is provided through the zone 1 thermostat. This thermostat is normally placed in the zone that has the greatest usage. In a residential installation, the best location would probably be the living room.

The zone panel will respond to a call from any thermostat, provided the call is for the same mode that the zone 1 thermostat is in. If zone 1 is on cooling, a call for heat from another thermostat will have no effect. When any zone calls, its zone damper opens and zones not called are closed. The system is started if it is not already on. When all the zones are satisfied, all dampers go to a fully open position and the system cycles off. This permits the fan to dissipate any residual heat that may be left in the furnace and allows fan-only operation.

72.11 ADVANCED COMMUNICATING ZONE SYSTEMS

Carrier Infinity Zone System

The Infinity zone control is designed to work with Carrier's Infinity line of products. The Infinity zone system consists of several intelligent communicating components:

- Infinity zone control (or user interface)
- Smart sensors
- Damper control module
- A variable-speed furnace or fan coil
- Two-stage air conditioner or heat pump
- Infinity packaged products

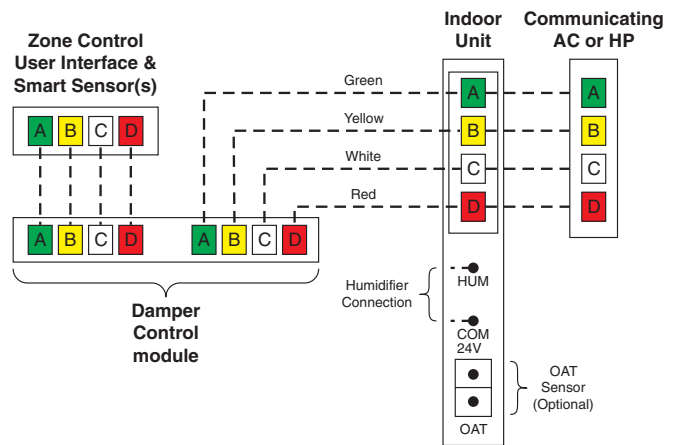

Figure 72-18 Four-wire connections for the Infinity zone control system.

The components continually communicate with each other via a four-wire connection called the ABCD bus. Commands, operating conditions, and other data are passed continually between components over the ABCD bus. Figure 72-18 shows the ABCD bus connections between communicating components. The communications allow for more intelligent system control. For example, the Infinity zone control knows the real-time airflow through each zone because the blowers communicate this information back to the control.

Unlike the other zone control systems discussed, the Infinity zone control is the component that would normally be considered the thermostat. The user interface that mounts on the wall is actually the system zone controller. The Infinity system does have a damper controller, but its job is simply to operate the dampers based on commands from the Infinity controller.

The Infinity zone control is also the user interface. It functions as a programmable thermostat as well as a system controller and zone controller. In a standard setup, the Infinity controller is used to program all the zones and enter the temperature settings for all zones. Temperature sensors that have no user interface are used in the other zones (Figure 72-19). Optional smart sensors can be used in place of the standard zone sensors. These allow users to change

Figure 72-19 Infinity remote room sensor.

Figure 72-20 Wiring of complete Infinity zone control system.

the temperature setting for a zone at the zone sensor rather than at the Infinity controller.

The wiring and connections for an Infinity zone control system are shown in Figure 72-20. The indoor unit, outdoor unit, zone control, and damper control are all connected with the four wires of the ABCD buss. The sensors are connected with two wires and the damper motors with three wires.

All Infinity furnaces or fan coils are variable speed and multistage. The infinity system controls the fan speed and system capacity to match the demands of the system, so bypassing air is not required. The control can be used with furnaces, air conditioners, heat pumps, or dual-fuel heat pumps.

New installations do not require jumpers or programming; the control recognizes the communicating components connected to the system and configures itself on initial power-up. First the control will locate all communicating components. Next, the system will open all dampers and perform a static pressure check. This process will take about 1½ minutes to complete. When completed, a screen will appear displaying the static pressure (in inches) across the equipment at the expected highest delivered airflow. If the static pressure is over 1 in, a warning will appear, but equipment operation and the True Sense dirty-filter detection operation will not be affected. After the static test, the control does a duct assessment. The duct assessment will measure the relative size of the ductwork, up to and through the dampers. These measurements are used to control the correct amount of airflow in the zoned system. Status messages will appear on the screen to indicate what the system is doing. The process will take approximately 1 minute per zone. The duct assessment will override a call for heat or cool. A duct assessment will automatically occur each day at a user-selectable time. The factory default time is 1 PM but may be changed by entering the Zoning Setup menu.

During the duct assessment, the system will first open all zones and drive the blower to 175 CFM/ton of cooling (or the minimum indoor unit's airflow, whichever is greater). It will then take a static pressure measurement. The system will then close all zones and open one zone at a time, taking a static pressure measurement for each zone. The system will then close all zones and take a pressure measurement, getting a value for the duct leakage up to and through the dampers. With these static pressure measurements, the system will calculate the relative size of each zone as well as the percent leakage through the dampers. At the end of the process, the display will show the relative size of each zone duct.

72.12 COMMUNICATING ZONE CONTROL SYSTEM OPERATION

The primary difference in operation between most other zone control systems and the Infinity zone control system is that the Infinity system is an intelligent communicating system. The zone controller is collecting real-time operating data and making decisions about system operation based on this data. Other systems rely on mode switches, jumpers, or programs that are configured at the time of installation. These systems can only respond to on or off signals. The Infinity can determine when the air filter is stopped up based on changes in the fan. Staging of multiple-stage equipment is done based on demand, rather than any predetermined temperature or zone arrangement. Air bypass is not required because the fan speed is varied based on the demand and the number of operating zones. The Infinity also responds to demands for dehumidification by reducing the fan speed and increasing the latent heat capacity of the evaporator coil. The Infinity controller has a service mode

Figure 72-21 This zone control panel uses wireless communication. (Courtesy of Jackson Systems, LLC)

that displays the system history and any system faults, allowing technicians to see faults when diagnosing system problems. All of this is done by collecting real-time operating data and making decisions.

72.13 WIRELESS ZONE CONTROL SYSTEM

One of the newest types of zone control systems uses wireless communication instead of wires. Figure 72-21 shows a wireless zone panel, while Figure 72-22 shows a wireless thermostat used with the wireless zone panel. No control wires are required between the thermostats, zone panel, and dampers. The zone panel does require power to operate and is wired to the control system of the air-conditioning equipment. Duct supply, return, and outdoor air tempera-

Figure 72-22 This wireless thermostat is used in conjunction with the wireless zone panel. (Courtesy of Jackson Systems, LLC)

Figure 72-23 Wireless Zone One single-zone damper. (Courtesy of Jackson Systems, LLC)

ture sensors are still wired as well. Since no control wires are required between the zone panel and the thermostats, thermostat placement is much simpler. The zone dampers require wired power to operate, but no control wires are necessary. Wireless zone systems are ideal for adding zone control to an existing system where pulling control wires would be difficult.

72.14 SINGLE-ZONE DAMPER SYSTEMS

A complete zone control system might be overkill if the problem is a single room or area that is overconditioned compared to the rest of the house. This can be solved using a system with a single zone damper that does not turn the heating or cooling system on but closes off the damper to the room when the temperature is satisfied to prevent overheating or overcooling. Figure 72-23 shows a wirelessly controlled Zone One damper for a single-zone system.

It uses a duct sensor located on the damper to sense if the air in the duct is warm air or cool. The control then operates the damper based on the signal from the wireless thermostat and the air temperature in the duct. If the Zone One thermostat is calling for cooling and the duct sensor determines there is cool air in the duct, the damper will power open; otherwise, the damper will remain closed. If the Zone One thermostat is calling for heating and the duct sensor determines there is warm air in the duct, the damper will power open; otherwise, the damper will remain closed. The wireless relay control module has LED indication to confirm the operating mode and damper position.

UNIT 72—SUMMARY

Residential zone systems have moved from a luxury reserved for only a few high-end homes to a viable strategy for comfort and economy in a much broader range of

applications. Many zoning products are available, from simple relay logic, two-position systems with air bypass to sophisticated communicating systems with variable air volume and capacity control. A zone system may be as simple as a two-zone system for a two-story house or as complex as a zone for every area in the house with different temperature and setback schedules for each area. A decade ago, technicians might have seldom been required to work on a zone system; today a technician is almost certainly going to need to work on residential zone systems.

WORK ORDERS

Service Ticket 7201

Customer Complaint: Basement Too Cold in Summer

Equipment Type: Basic Zone Control Using Two-Position Dampers, Single-Stage Heating and Cooling

A technician is called to look at a zoned system with three zones: one in the finished basement, one in the living areas, and one in the bedrooms. The basement is staying below 70°F even though the thermostat for that zone is set to 78°F. The technician notices that the system is operating and cold air is coming out of the basement diffusers. A visual check of the damper shows that it is open. However, a voltage check at the damper indicates that it is receiving a signal to close. The technician determines that the damper is stuck open and recommends replacing the damper.

Service Ticket 7202

Customer Complaint: No Heat

Equipment Type: Heat Pump with ECM Motor and an Advanced Zone Control

A technician is called to look at a zoned heat pump system that is not heating. The technician notices that all zones are calling for heat, but no air is coming out of the registers in one zone. Air is coming out of the other zones, but it is not warm. The temperature outside is above the heat pump balance point. A check of the outside unit reveals that it is not operating and the high-pressure switch has tripped. The technician resets the pressure switch and the compressor comes on. Heat is now coming out of two zones, but one zone still has no airflow. The technician checks the damper and finds it closed even though it is receiving a signal to open. The technician concludes that the stuck damper caused an airflow problem when only that zone was calling, which led to the high-pressure switch tripping. The tripped pressure switch then prevented the system from operating and heating the remaining zones. The technician recommends replacing the stuck damper.

Service Ticket 7203

Customer Complaint: Delay in System Starting

Equipment Type: Advanced Zone Control

A customer is concerned because the system waited for several minutes before it came on after she adjusted the temperature. The customer had just returned home from running and heard the system cycle off. Because she was hot, she adjusted the temperature down several degrees to bring on the air conditioner. However, nothing happened. While the customer is on the phone with the service company, the system comes on. The technician explains that the system has a built-in off-cycle timer that makes the system stay off for 5 minutes anytime the system cycles off. This is for the protection of the compressor.

Service Ticket 7204

Customer Complaint: Hot Air in Cooling Mode

Equipment Type: Basic Zone Control on Heat Pump

A technician is called to look at a newly installed system that is delivering hot air in the cooling mode. The technician notices that the heat pump is operating in the heating mode even though the master thermostat is set for cooling. A look at the diagram for the outdoor unit shows the reversing valve should energize in cooling with the O terminal. Checking the zone panel jumpers, the technician discovers that the reversing valve switchover jumper has been set to reverse in heat instead of cooling. The technician moves the jumper to the cooling position and the heat pump operates correctly.

Service Ticket 7205

Customer Complaint: No Airflow in the Bedroom Zone

Equipment Type: Advanced Zone Control System, Single-Stage Heating and Cooling

A technician is called to look at a newly installed system. The zone serving the bedroom area is not delivering any air. The technician notices that there is no air delivery in the zone, even with the system switch set to off and the fan switch set to on. A check of the zone damper shows it is closed. A voltage check shows voltage between the common and close terminals on the damper. At the zone control, a voltage check shows voltage between the common and open terminals. The technician looks at the wire colors and determines that the open and close signal wires to the zone damper have been reversed at the damper. The wires are swapped at the damper and the system operates correctly.

UNIT 72—REVIEW QUESTIONS

1. Why are zone control systems used?
2. List the components found in a basic zone control system.
3. What two general criteria are used to select zones for a building?
4. Explain the reason zone control systems need a method for handling excess air.
5. List the methods of handling the excess air in a zone system.
6. Discuss the disadvantages of air bypass.
7. Explain the concept of variable air volume in a zoning system.
8. Explain the difference between two-position and modulating damper control.
9. Explain how a barometric damper operates.
10. List several types of zone dampers.
11. Explain the difference between a basic zone control system and an advanced zone control system.
12. The PIAB jumper on zone 1 of a Lennox Harmony III control is set at 40 percent. The minimum airflow is 900 CFM and the maximum is 1,800 CFM. How much air will this zone receive? Show all work.
13. Explain the purpose of using a dump zone in a zone control system, and give an example.
14. What is the difference between a communicating zone control system and a basic zone control system?
15. What is the purpose of the master thermostat in the basic zone control system?
16. What is the purpose of discharge air sensors?
17. What is the purpose of the outdoor air sensor on a zone control system?
18. How are motorized dampers controlled when they are used as bypass dampers to relieve a pressure differential across the blower?
19. Describe the added features available on some basic zone control systems.
20. How is an Infinity zone control system configured?

UNIT 73

Testing and Balancing Air Systems

OBJECTIVES

After completing this unit, you will be able to:

1. explain why TAB (test and balance) is critical to the operation of an air-conditioning system.
2. explain why TAB is critical to energy consumption of an air-conditioning system.
3. list the organizations involved in the TAB industry.
4. list the instruments used to perform TAB procedures.
5. explain proper use of instruments used in TAB procedures.
6. describe TAB procedures.

73.1 INTRODUCTION

Test and balance, sometimes referred to as test, adjust, and balance or just TAB, is the adjustment of the air side and water side of an HVACR system to the operational specifications of the designer's original intent. In some cases these adjustments must be redone due to seasonal changes or changes in the structure. This unit will discuss the air side of an HVACR system.

Commercial projects recognized the need for TAB as early as the 1960s. Originally the installation contractor completed any test and balance that was needed at start-up along with other commissioning activities. As commercial projects grew and indoor air quality became a more clearly defined issue, independent TAB contractors began to operate as a quality-control check on the system and the project. The TAB industry has grown into a large part of the commercial HVACR industry. There are many measurements and adjustments that are specific to testing and balancing that are not normally performed in regular HVACR work. Technicians working for TAB contractors go through extensive training and certification, which can take up to 5 years to complete.

The residential TAB market has seen large growth recently due to energy costs and increased health concerns related to residential indoor air quality. The largest energy consuming appliance in the home is the HVACR system, and most of these systems are estimated to have a 30 percent loss of efficiency due to improper air-side design and installation. Some states and the federal Department of Energy have adopted standards for the testing of HVACR residential systems and have offered incentives to builders who will have their homes certified under the programs. At the local level, many power companies offer TAB analysis for little or no cost to the consumer, in hopes of lowering energy consumption.

Health concerns have increased in the residential environment as home construction techniques and materials have improved. As homes have become increasingly tighter due to energy concerns, the infiltration of outside air has been reduced, causing indoor pollutants and stagnant air to affect those more susceptible to such pollutants, such as infants and the elderly. Many respiratory afflictions, such

as asthma, are on the rise, while at the same time studies show indoor pollution rising as well. A combination of ventilation and filtration can be used to introduce filtered, fresh air into the house. TAB is seen as part of the solution because the airflow in a properly balanced system is more predictable and controllable. A home that is properly balanced will prevent air from stagnating and help to reduce pollutants by the conditioning and filtering of the indoor air.

73.2 TAB ORGANIZATIONS

In the TAB industry there are several organizations committed to developing standards, procedures, training courses, and to certification of technicians and contractors. As in the rest of the HVAC industry, these organizations overlap on missions and compete in several ways. Associated Air Balance Council (AABC), National Environmental Balancing Bureau (NABB), and Testing Adjusting and Balancing Bureau (TABB) are the major organizations that specialize in test and balance of HVAC systems. Other groups are also involved in TAB but not exclusively. ASHRAE, the American Society of Heating and Air-Conditioning Engineers, is a good example of one of these organizations.

The Associated Air Balance Council is the oldest of the three and started in 1960s. The AABC is an independent association, and its member's firms can have no affiliation with manufacturers or HVAC contractors. Member firms must also enroll their technicians in AABC training courses. These courses, combined with 4 years of industry experience, lead to technician certification. AABC publishes standards for the industry and a newsletter. Member firms are required to participate in a quality-assurance program where the association receives feedback from the client on the work performed.

The National Environmental Balancing Bureau was started in the 1970s. NEBB certifies firms and provides training at their Arizona facility. The training includes labs and practical exams. NEBB also publishes standards and manuals that cover all aspects of the TAB industry.

The Testing Adjusting and Balancing Bureau is the youngest of the three. TABB is an organization started in 2001 to work with Sheet Metal and Air Conditioning

Contractors Association (SMACNA). TABB publishes standards, manuals, and a newsletter, and all these publications are produced in partnership with SMACNA. TABB certifies technicians, supervisors, and contractors because TABB's approach is that everyone involved in the project be TABB trained from designer to installer. TABB produces industry training for designers, supervisors, and tradesmen. TABB training is offered to tradesman at the union hall during apprenticeship and as continuing education throughout their career. TABB takes a "total quality" approach instead of a "quality by inspection" approach. This is possible because of the relationship TABB has with all of the participants in the project.

Although each organization takes a different approach, the outcome of having a well-installed and energy-efficient system that provides conditioned air and comfort to the people using the space is met by using standards and methods developed by these associations. Although many smaller projects may not use independent firms or union contractors, TAB is a critical part of the commissioning of each installation and modification of all HVAC systems. Not testing and balancing every system adds to the energy cost for the owner and society, as well as possible medical costs for the occupants.

73.3 TAB TEST INSTRUMENTS

In smaller companies, contractors may have the start-up technician perform the required TAB tests. Measurements taken for TAB applications are temperature, pressure, velocity, rotating speed (rpm), and electrical. Many instruments used by service technicians are also used by TAB technicians, such as digital thermometers, psychrometers, anemometers, manometers with a pitot tube, and digital multimeters. Other instruments used in TAB tests that would not be commonly found on a typical service van are chronometric tachometers, digital or analog capture hoods, and air-differential pressure gauges. These are specialized tools that TAB technicians may choose to use depending on the application.

TECH TIP

As with most test instruments on the market today, the accuracy of digital test equipment is better and the ease of use is often greatly improved over analog models. The sling psychrometer is the clearest example. The drawback to digital instruments is price, and in some cases digital versions can run 10 times more than analog versions. This is why sling psychrometers are still in use today.

73.4 TEMPERATURE MEASUREMENTS

Temperature measurements are taken to compare return- and supply-air temperature in the conditioned space and entering- and leaving-air temperature at the furnace or evaporator coil. In some cases, suction and discharge

temperature are also measured by TAB technicians to confirm proper system refrigerant charge. Instruments used for these measurements are as follows:

Glass-tube thermometers (Figure 73-1) are available in a number of ranges, scale graduations, and lengths. They have a useful range from -40° to over 220°F .

Dial thermometers are available in two general types: bimetal stem (Figure 73-2) and remote bulb with flexible capillary tube (Figure 73-3). Bimetal stem thermometers use a spiral formed bimetal inside the tube. As the bimetal expands and contracts, it produces a

Figure 73-1 Glass-tube thermometers: (a) in protective case; (b) with glass tube exposed.

Figure 73-2 Bimetal dial thermometer reading air temperature leaving a supply-air register.

twisting motion that moves the needle on the thermometer. The remote bulb model permits temperature measurements from a remote location. The bulb and capillary tube are liquid or gas filled, and the fluid expands or contracts to operate a Bourdon tube. Dial thermometers usually have a longer reading time lag than glass-tube thermometers.

Digital pocket thermometers (Figure 73-4) are electronic, digital replacements for the typical dial-type pocket thermometer. They are generally more durable and more accurate than mechanical stem-type pocket thermometers.

Figure 73-3 Remote bulb and capillary-tube dial-type thermometer. (Palmer Wahl Instrumentation Group)

Figure 73-4 Digital pocket thermometer.

Electronic thermometers have interchangeable probes to permit more accurate reading in selected ranges. There are three basic types of temperature-sensing elements used: resistance temperature detectors (RTDs), thermistors, and thermocouples. The meters are built for use with a particular type of sensor. Thermometers with interchangeable probes, and multiple connections are useful for reading temperatures at a number of locations. They can also be used to read the temperature difference between two probes for comparative temperature readings like superheat, subcooling, or delta T measurements (Figure 73-5).

Figure 73-5 This dual-input electronic thermometer can be used for comparative temperature measurements like superheat, subcooling, and delta T.

Figure 73-6 This electronic thermometer uses thermistor sensors. (Courtesy of Cooper-Atkins Corporation)

Resistance temperature sensors are wound wire with known resistance values. The resistance of the wire increases as its temperature increases, producing a very accurate reading. RTD sensors typically have a very narrow operating range. They also have a longer time lag than the thermocouple type due to the time required for the wire's temperature to change.

Thermistor sensors also change resistance with temperature, except they use a semiconductor instead of wire. Most thermistors used for electronic thermometers decrease in resistance as their temperature increases. Thermistor sensors typically read faster than RTD sensors. Figure 73-6 shows an electronic thermometer that uses thermistor-type sensors.

Thermocouple sensors produce a small DC voltage that is proportional to the temperature difference between the two ends of the thermocouple. Thermometers that use thermocouple sensing devices are calibrated to read this voltage as temperature and read temperature directly. There are two common types of thermocouple sensors: type J and type K. Figure 73-7 shows an electronic thermometer that uses thermocouple sensors.

SERVICE TIP

Electronic thermometers with dual inputs make reading differential temperature measurements such as superheat, subcooling, and delta T much easier. Most dual-input electronic thermometers have a function that automatically displays the difference between the two temperature probes.

Figure 73-7 Thermocouple thermometers.

Figure 73-8 Sling psychrometer.

73.5 ENTHALPY MEASUREMENTS

Enthalpy measurements are calculated from wet-bulb and dry-bulb temperatures. Measurements are then plotted on a psychrometric chart to find the enthalpy of air in the measured space or to compare entering-air enthalpy to leaving-air enthalpy across an evaporator coil. Instruments used are, the sling psychrometer and the electronic hygrometer.

The sling psychrometer consists of two glass thermometers, one of which has a wick wetted by water surrounding the bulb. The frame that supports the two thermometers is hinged to permit revolving the wetted instrument in the air. The unit should be whirled at a rate of two revolutions per second for most accurate results. Readings are taken on both thermometers after the temperatures have stabilized. Readings indicate dry-bulb and wet-bulb temperatures, which can be plotted on a psychrometric chart to determine numerous properties of the air sampled. Figure 73-8 shows a sling psychrometer.

The electronic hygrometer is usually constructed with a thin-film capacitance sensor. As the moisture content and temperature change, the resistance of the sensor changes proportionately. These instruments usually read directly in relative humidity. No wetted wick is necessary, and the instrument can remain stationary when readings are taken. Figure 73-9 shows an electronic hygrometer.

Figure 73-9 Digital psychrometer. (Courtesy of Extech Instruments, A FLIR Company)

73.6 PRESSURE MEASUREMENT

The pressure measurements that technicians take while testing and balancing systems range from the air pressure inside ductwork to the pressures in a refrigeration system. The instrument used to take the pressure reading depends largely upon the level of the pressure. Inclined manometers, magnehelic gauges, and digital manometers are used for small pressures of less than 1 in wc, such as the air pressure drop across a coil. Bourdon tube gauges are used for higher pressures measured in psig, such as the refrigerant pressure drop across a refrigeration system component.

Bourdon Tube Gauges

Calibrated pressure gauges typically use a Bourdon tube assembly for sensing pressure (Figure 73-10). The Bourdon tube may be constructed of stainless steel, copper, or

bronze. The dials are available with pressure, vacuum, or compound gauges showing both pressure and vacuum. Gauges are used for checking pump pressures; coil, chiller, and condenser pressure drops; and pressure drops across orifice plates, valves, and other flow-calibrated devices.

Most flow measurements require determining the pressure drop across a component. Pressure-differential readings can be done with two separate gauges or a single gauge with a rotating dial or a special differential pressure gauge. When two gauges are used, it is essential that the gauges be calibrated to each other. This can be checked by comparing the two gauges when there is no flow and they are reading only static pressure. They should register the same pressure.

A single gauge with a rotating dial can be used to measure differential pressure. The gauge is installed with two valve connections: one to the lower of the two pressures and one to the higher pressure. The low-pressure line is opened while the high-pressure line valve remains closed. The gauge dial is then rotated to zero. The low-pressure valve is closed and the high-pressure line valve opened. The pressure reading will be the difference between the two

Figure 73-10 The most common type of gauge used for higher pressure is the Bourdon tube gauge.

pressures. For example, if the lower pressure is 15 psi and the higher pressure is 20 psi, the gauge will read 5 psi.

A differential pressure gauge uses two inputs and measures the difference between the two pressures.

Manometers

U tube manometers (Figure 73-11) are used for measuring gas pressure. When not connected, both ends of the U tube are open to the atmosphere. The tube is partly filled with liquid. Both tubes register zero when they are both open to the atmosphere. When one tube is attached to gas pressure, the side connected to gas pressure drops and the open side rises. The pressure is indicated by the difference in the height of the two columns. U tube manometers are recommended for measuring pressures above 1.0 in wc up to 15 in wc.

Inclined Manometers

The inclined manometer (Figure 73-12) is useful for measuring static pressure, velocity pressure, and total pressure in a duct when connected to a pitot tube. The pitot tube is constructed with a tube-in-a-tube design (Figure 73-13).

Figure 73-11 U tube manometer.

Figure 73-12 Inclined/vertical manometer. (Courtesy of Dwyer Instruments, Inc.)

Figure 73-13 Detailed construction of a pitot tube.

Figure 73-14 Standard manometer connection to a pitot tube.

When pointed against the airflow, the inner tube measures total air pressure and the outer tube measures static pressure. The difference between the two pressures is the velocity pressure (Figure 73-14). For air at temperatures close to normal room temperature, the air velocity can be calculated using the formula: $4005 \times \text{square root of velocity pressure}$. For example, an airstream with a velocity pressure of 0.16 in wc would have a velocity of: $4,005 \times \text{square root of } 0.16 = 4,005 \times 0.4 = 1,602 \text{ fpm}$. Charts are also available for converting velocity pressure to fpm (ft/min) (Figure 73-15).

SERVICE TIP

Digital manometers are available that can read in the same pressure ranges as inclined manometers. These are much easier to transport and use than traditional inclined manometers.

73.7 AIRFLOW

Airflow measurements measure the rate of airflow. The two most common airflow measurements are air velocity, in feet per minute (fpm), and air volume, in cubic feet per minute (CFM). Feet per minute measures how fast the air is traveling. CFM measures the volume of airflow. Having the correct air volume, CFM, is crucial to any air-conditioning application.

Air Velocity

Air velocity is not the same through all parts of the duct. It tends to move faster toward the middle and slower toward the outside of the duct. A procedure called traversing the duct is used to get an accurate velocity reading. Readings are taken at several positions in the duct to get the average air speed through the duct. The combination of the inclined manometer and pitot tube is used in measuring air volume in a duct by making a traverse (Figure 73-16).

Figure 73-15 Chart for determining air velocity pressure. (Courtesy of Dwyer Instruments, Inc.)

Figure 73-16 Round duct traverse.

Air Volume

The air volume can be calculated in cubic feet per minute using the velocity in feet per minute and the cross-sectional area of the duct in square feet (ft²). The formula is:

$$\text{CFM} = \text{area} \times \text{velocity}$$

For example, a 12 in × 24 in duct has a cross-sectional area of 2 ft²:

$$\begin{aligned} 12 \times 24 &= 288 \text{ in}^2 \\ 288 \text{ in}^2 / 144 \text{ in}^2/\text{ft}^2 &= 2 \text{ ft}^2 \end{aligned}$$

If the velocity through this duct is 350 fpm, the air volume is 2 ft² × 350 fpm = 700 CFM.

Air Velocity/Volume Measuring Instruments

Inclined manometers and pitot tubes read airflow by reading the pressure in a duct. This will not work once the air has left the duct and is entering the room. Instruments are available that read fpm, CFM, or both directly without having to read a pressure in a duct. Some direct-reading airflow instruments used are the rotating vane anemometer, the thermal anemometer, the velometer, and the flow hood.

The rotating-vane anemometer consists of a light-weight air-propelled wheel, geared to dials that record the linear feet of airflow passing through the instrument. Anemometers read feet of air. The instrument is placed in the airstream and readings are then taken for a measured amount of time. The anemometer reading is divided by the time to arrive at a velocity reading in fpm. Anemometers can be either analog or digital. The analog instrument is a direct reading with the choice of a number of different velocity scales. The digital instrument will automatically average the readings and display the velocity readout in fpm (Figure 73-17).

The thermal anemometer operates on the principle that the resistance of a heated wire will change with its temperature (Figure 73-18). The probe is placed in the airstream

(a)

(b)

Figure 73-17 Two examples of a rotating vane anemometer.

and the velocity is indicated on the scale of the instrument. Thermal anemometers can be used for measuring very low velocities of air, such as that found in a room. They can also be used in a duct to determine air velocity.

Figure 73-18 Thermal anemometer.

A velometer reads the instantaneous speed of the air, not the averaged speed. A velometer is similar to the speedometer on a car, which tells how fast the car is going at that instant. Velometers are also available in both analog and digital form. Many digital velometers can function as either a velometer or an anemometer.

The flow hood is useful in accurately determining the airflow volume in CFM from an outlet (Figure 73-19). It completely collects the air supply and directs it through a 1-ft² opening where a calibrated manometer provides the CFM readout. Hoods should be selected to as nearly as possible fit the diffuser being measured and have a tight seal around the opening. Flow hoods are considered the most accurate measurement of airflow through registers and grilles.

73.8 ELECTRICAL MEASUREMENTS

Electrical measurements are taken to determine voltages, current, and wattage used by electrical loads such as electric motors or electric furnaces. The wattage can be used to find variables such as BTU or rpm (revolution/minute), which are used in duct system performance equations. The instrument used may display units of measure such

Figure 73-19 Flow-measuring hood.

as volts, amps, or watts, and these units are converted by technicians as needed. Common electrical meters include the digital multimeter and the clamp-on ammeter.

The digital multimeter is useful for making electrical measurements in the field. Most meters have several scales, including volts, ohms, and amperes. Multimeters typically read small currents inline, such as milliamps.

The clamp-on ammeter is used to read large currents. The clamp-on transformer jaws permit reading current flow without disconnecting the circuit. Care must be exercised when reading ampere flow to only clamp onto one wire at a time. Enclosing two wires may result in a zero reading. The amp draw of a blower motor can be used as a general indicator to show the amount of air that a blower is moving. The amp draw increases as the fan moves more air and decreases as the blower moves less air.

A wattmeter is needed to take accurate wattage readings in most AC circuits. Apparent power can be determined by multiplying the voltage and amperage, but the apparent power in an AC circuit is usually higher than the actual wattage because of the effects of inductive and capacitive reactance. Purely resistive AC circuits are an exception because they are not subject to inductive or capacitive reactance.

73.9 ROTATION MEASUREMENT

Rotation measurement of fans by TAB technicians may be required to determine fan rpm. The airflow rate produced by a fan is directly related to fan speed. Measuring

Figure 73-20 Tachometer: (a) front view; (b) side view.

the fan speed before and after any adjustments ensures the proper adjustment is made. Instruments used to measure rotation are the mechanical tachometer, digital photo-tachometer, the chronometric tachometer, and the stroboscope.

A mechanical tachometer requires contact to the center of the rotating shaft that is being measured (Figure 73-20). A rubber tip transfers the rotational motion to the tachometer, which reads in revolutions per minute.

The chronometric tachometer combines a revolution counter and a stopwatch in one instrument. The spindle is placed in contact with the rotating shaft. This sets the meter hand to zero and starts the stopwatch. After a fixed amount of time, usually 6 seconds, the counting mechanism is automatically uncoupled, and the instrument can be removed from the shaft and read.

A digital photo-tachometer uses reflective tape on the outside of the rotating device. It calculates the speed by measuring the frequency of the reflective tape passing by the stationary position of the photo tachometer. The instrument is battery operated and uses a digital display to show the speed in rpm. Digital photo-tachometers can take measurements that contact tachometers cannot take because they do not require physical contact. Some models

Figure 73-21 This tachometer can be used for either contact or non-contact RPM measurement. (Courtesy of Extech Instruments, A FLIR Company)

Figure 73-22 Digital photo-tachometer. (Courtesy of Extech Instruments, A FLIR Company)

can save the readings in memory. Figure 73-21 shows a tachometer that combines contact measurement, photo tach measurement, and infrared temperature measurement. Figure 73-22 shows a digital photo-tachometer.

The stroboscope is an electronic tachometer that uses an electronically flashing light. The frequency of the light flashes can be adjusted to equal the frequency of the rotating object. When the two are synchronized, the rotating object appears to be standing still. The rpm value can then be read on the stroboscope's dial Figure 73-23.

73.10 USING TEMPERATURE RISE TO MEASURE SYSTEM AIRFLOW

One of the simplest ways to measure airflow is the temperature-rise method. One advantage to this method is that the equipment used in the measurement is standard

Figure 73-23 The gear on the back of the pump motor appears “frozen” by the stroboscope, which shows the flashes per minute.

on all service trucks. Using the temperature-rise method on a heating system is straightforward because it is entirely a sensible heat process. All the heat that goes into the air changes the air temperature. Dry-bulb temperature measurements are taken both of entering and leaving air, and the difference of the two numbers gives the technician the TD, or temperature difference.

Entering air temperature – leaving air temperature
= temperature difference

Temperature-Rise Measurements

Find the furnace output ratings from the equipment information sheets. These should be listed in BTU/hr. The CFM can be calculated using the heat output in BTU/hr, the temperature difference, and 1.08, which is the constant for standard air. The factor 1.08 is the mathematical combination of all the other factors in the formula: $1.08 = 60 \text{ min/hr} \times 0.075 \text{ lb/ft}^3 \times 0.24 \text{ BTU/lb}$. To calculate CFM:

$$\text{CFM} = \frac{\text{furnace output in BTU/hr}}{(\text{TD} \times 1.08)}$$

Air-Conditioning System Temperature Drop

The temperature difference across an air-conditioning coil cannot be used to calculate airflow because all the system

capacity does not go into changing the air temperature; some capacity is used to condense water on the evaporator coil. The system capacity and the amount of latent cooling versus sensible cooling varies depending upon the system operating conditions, making temperature-drop calculations inaccurate.

Wet-bulb temperatures can be used to find the enthalpy of the air entering and leaving the evaporator. These measurements can be used to calculate the total system capacity. However, since the system capacity is not fixed, but varies depending upon its operating conditions, the enthalpy change through the evaporator coil is not an accurate way to determine system airflow.

TECH TIP

TAB technicians are keenly aware of the impact that improper unit sizing has on occupants and society as a whole because their training is focused on efficiency and indoor air quality. Many times “rule of thumb” sizing is used by untrained workers to speed a project along. Problems with these systems often stick out like a sore thumb once TAB technicians take their measurements and apply formulas on those units that have been sized using a rule of thumb. Problems resulting from improper sizing can affect the reputation of the worker and the employer.

73.11 USING TOTAL EXTERNAL STATIC PRESSURE TO MEASURE SYSTEM AIRFLOW

The amount of air moved by any blower or air-conditioning component containing a blower is dependent on the pressure that the blower is working against. The total difference in static pressure between the supply side of the blower and the return side of the blower is called the total external static pressure. In general, the higher the external static pressure on the blower, the lower its CFM output.

The airflow a blower is moving in a system can be accurately determined by measuring the pressure drop across the blower and comparing that pressure to the manufacturer’s specifications. To determine the amount of air a blower is moving, do the following:

1. Measure the total external static pressure difference across the blower.
2. Compare the external static pressure difference across the blower to the manufacturer’s specifications to determine the system airflow.

Figure 73-24 shows how to measure the pressure drop across a blower. For example, using Table 73-1 to check the blower performance of a blower operating on high speed against a total external static pressure of 0.3 in wc, we see that it can move 1,025 CFM at this pressure. The same blower operating against 0.5 in wc external static pressure can move only 915 CFM.

Figure 73-24 The static pressure difference across a blower can be used to determine the airflow through the blower.

Table 73-1 Blower Performance Data

CFM	High	Medium	Low
0.1 in wc	1,135 CFM	860 CFM	465 CFM
0.2 in wc	1,085 CFM	825 CFM	500 CFM
0.3 in wc	1,025 CFM	780 CFM	545 CFM
0.4 in wc	965 CFM	750 CFM	570 CFM
0.5 in wc	915 CFM	680 CFM	600 CFM

73.12 USING STATIC PRESSURE DROP TO MEASURE AIRFLOW

Any component in the airstream causes a pressure drop across it. This pressure drop can be used to determine the CFM traveling across the component if you have the manufacturer's

Table 73-2 Coil Airflow Data

CFM	Dry Coil Δp	Wet Coil Δp
600	0.10 in wc	0.11 in wc
700	0.12 in wc	0.12 in wc
800	0.15 in wc	0.15 in wc
900	0.17 in wc	0.18 in wc
1000	0.20 in wc	0.22 in wc
1100	0.25 in wc	0.26 in wc
1200	0.29 in wc	0.30 in wc
1300	0.33 in wc	0.35 in wc
1400	0.38 in wc	0.40 in wc
1500	0.43 in wc	0.46 in wc
1600	0.48 in wc	0.51 in wc

specifications for that component. Measuring the pressure drop across a component like a coil or filter works backward from the blower. In general, higher pressure drops across a device indicate that more air is moving through it. For example, measuring the static pressure drop across a coil and comparing it to the manufacturer's literature can show the amount of air moving across it. Table 73-2 shows the airflow characteristics for an evaporator coil. A measured dry-coil pressure drop of 0.15 in wc would mean that 800 CFM are moving across the coil, while a measured pressure drop of 0.25 in wc would indicate that 1,100 CFM are moving through the coil.

SERVICE TIP

The pressure drop stated in manufacturers' literature assumes clean components. A centrifugal fan with the cups full of dirt will not move as much air, causing a lower than normal pressure drop for that blower. The blower data will indicate that the fan is moving more air than it really is. Other components such as coils and filters will have an increased pressure drop when they are dirty.

73.13 USING VELOCITY PRESSURE TO MEASURE AIRFLOW

Sometimes it is necessary to measure the airflow moving through a section of duct. This is done using a manometer or magnehelic and a pitot tube to measure the velocity pressure. The pitot tube picks up both the total pressure and the static pressure. Velocity pressure is the difference between the two. Place the total-pressure tube on the high-pressure input of the manometer and the static pressure tube on the low-pressure input of the manometer to read the velocity pressure. Since air velocity is not steady, but is different in different parts of the duct, an average, or traverse, will need to be taken. This can be easily done using a digital manometer that offers real-time averaging. For normal room

temperatures, the air velocity can be determined using the formula:

Velocity in feet per minute = $4,005 \times \sqrt{\text{velocity pressure}}$.

Once you have the velocity, multiply the velocity times the cross-sectional area of the duct. For example, a 12 x 24 in duct with an air velocity pressure of 0.04 in wc:

$$\begin{aligned} 4,005 \times \sqrt{0.04} &= 4,005 \times 0.2 = 801 \text{ FPM velocity} \\ 12 \times 24 \text{ in} &= 288 \text{ in}^2 = 2 \text{ ft}^2 \text{ area} \\ 801 \text{ FPM} \times 2 \text{ ft}^2 &= 1,602 \text{ CFM.} \end{aligned}$$

73.14 MEASURING AIRFLOW AT REGISTERS AND GRILLES

The airflow from a register or grille can be measured using an anemometer. The velocity needs to be read at several points and averaged. A digital rotating-vane anemometer can keep a real-time average, making this much easier. The air velocity is multiplied by the grille-free area to arrive at the CFM. The free area is the area of the grille that is not taken up by the louvers. The free area can be as little as 50 percent of the overall area. Drop-ceiling perforated grilles typically have a free area of on 50 percent. The difficulty in using this method is in knowing what the free area is. The only way to know accurately is to have the manufacturer's specifications.

The easiest and most accurate method for measuring the airflow at registers and grilles is with a flow hood. The flow hood is placed over the register or grille and all the air moving through the register or grille must pass through the flow hood. The flow hood can easily calculate the CFM since its free area is known. The CFM is read directly on the flow hood.

SERVICE TIP

A cone or pyramid with a known area can be fabricated and placed over the register. This eliminates the need to determine the free area. The airflow through the opening of the measurement cone is generally more even than at the face of the register, making it easier to take an average velocity reading.

73.15 DUCT LEAK TESTING

The T in TAB is for testing, and this starts with a general inspection. If the testing is part of the commissioning of a new or modified system, then comparisons should be made between the designer's plans and the physical layout of the project. This comparison will point to possible problems before measurements are actually taken and could save the technician considerable time. If the testing is taking place on an existing system, then a review of designer plans may not be an option. In this case, gathering manufacturer's data is the first step prior to inspection. System tonnage, blower CFM, and heat exchanger data should be noted by the technician on the paperwork for easy reference. This

information will be included later in the report submitted to the client along with the findings of the test.

The system should be started prior to testing to confirm airflow at the return and that the system is supplying airflow at the supply terminals. At this point the technician is simply concerned about the presence of airflow. In the balancing phase of TAB we will measure for quantity of airflow. Low or no flow can indicate duct or system problems. Once flow is confirmed, an amp draw reading should be taken before shutting the system down. If the amp draw is not in range of what the manufacturer requires, restrictions above design specifications or duct leaks may be present. Again this will give the TAB technician an indication that the system has apparent problems before starting the duct leak test.

Once these preliminary checks are made, the duct leak test can be done. Duct leakage is determined by blocking all duct outlets, pressurizing the duct, and measuring the amount of air that is required to maintain that pressure. As air leaks out, more air is let in to maintain the pressure in the duct system. In theory, no additional airflow should be required to maintain the pressure once the duct has been pressurized.

There are several ways to complete a leak test, but the standard method is the use of an orifice tube. The orifice is certified and designed for a specified flow curve. A pressure source is installed to pressurize the duct system. This is normally an axial fan with an inlet damper to control airflow and limit pressure to the duct system. Two manometers are used during these checks. One will be installed to measure pressure drop across the orifice, and the other will measure static pressure in the duct system at the farthest distance from the orifice. Pressure supplied to the duct system should not exceed maximum design ratings that are specific to each system. The technician should read the pressure drop across the orifice and then compute the flow rate using the flow curve data. The actual leakage rate can then be compared with the allowable leakage rate of the duct system. Most systems should have a loss rate no greater than 2 percent. A review of standards and local codes should be used to determine each project's maximum loss rate.

Once the inspection and leak tests are completed, a report should be generated for the client. If the duct system is out of design tolerance, the system should be corrected to meet design conditions before attempting to balance it. Most duct systems are installed in a unconditioned space, so ducts that leak will increase energy costs and prevent the system from controlling humidity, temperature, and indoor air quality to the efficiency level that the system was designed to meet.

73.16 SYSTEM BALANCING

Balancing in its broadest meaning includes testing and adjusting a system to produce its design specifications. It is the final step in the HVAC project prior to occupancy and use by the owner. It is an important phase of the work, since many components from many sources have been assembled to perform a valuable service. Usually equipment adjustments and control settings are necessary to prepare for the desired operation.

General concepts and measurements should be understood before focusing on particular systems. It is easier to balance a heating system during cold weather and a cooling

system during warm weather, but this is not always possible. It is recommended that the first balance be made when the job is completed or before occupancy and the final balance made during a period as near design temperature conditions as possible.

All duct systems should have balancing dampers installed at the trunk of the duct system. All branches should have the airflow adjusted at these dampers. Supply registers should be used as balance adjustment points only if a branch feeds more than one supply register. If supply registers are used as balancing dampers, they will produce excessive noise in the space. If a duct system has no balancing dampers installed at the trunk, the owner should be notified in writing that the system cannot be properly balanced without their installation.

The blower must be sized and adjusted to supply the needed output for the whole duct system. The blower is sized by the design engineer, but the blower rpm may need to be adjusted by the technician to meet actual demand. The TAB technician is expected to measure the CFM produced by blower and complete the adjustments necessary for the actual performance to match the design performance.

73.17 GENERAL AIR-BALANCING PROCEDURE

First, collect complete information about the installation. This should include unit specifications, control systems details, job layout, and airflow quantities for each register and grille. Examine the entire installation. Look for problems that need to be corrected, such as leaky ductwork, missing parts, and incomplete wiring.

After gathering system data, the overall system airflow should be measured and compared to design specification. There is no point in adjusting the airflow to individual areas until the overall system airflow is correct. Open all dampers, operate the system, and measure the overall system airflow in CFM. Compare the actual system airflow to the design airflow. If the actual delivered airflow is more than 5 percent out of specification, adjust the blower speed to achieve design airflow.

The next step is to compare the airflow delivered in the space to the airflow at the blower. Use a flow hood, velometer, or anemometer to measure the airflow at each supply register and return grille. The sum of all the CFM measurements at the individual return grilles should be within 10 percent of the system CFM at the blower. Leaks in the return-air ducts will cause the air entering the return grilles to be less than the total amount of air the blower is moving. If the difference is greater than 10 percent, the return ducts should be checked for leaks. Similarly, the sum of all the CFM measurements at the individual supply registers should be within 10 percent of the system CFM at the blower. Leaks in the supply-air ducts will cause the air leaving the supply-air registers to be less than the total amount of air the blower is moving. If the difference is greater than 10 percent, the supply-air ducts should be checked for leaks.

Once the total delivered airflow is within specification, the supply register measurements should be compared to design specifications for each area. Dampers can now

be adjusted to achieve the correct airflow at each register. Since the adjustments are being made starting with all dampers open, start by partially closing the dampers to registers that are delivering too much air. Begin with the register that exceeds design specifications the most.

Physical adjustments to dampers change the overall system resistance, affecting the CFM throughout the duct system.

Ideally, measurements should be taken after each adjustment to see the effect of the adjustment on the entire system. However, this can be very time-consuming. An alternative is to measure only the output of the zone you are adjusting until it is correct and then retake the overall system CFM to ensure that the overall system airflow has not dropped as a result of the adjustment. Recheck all measurements periodically to see the overall effect of your adjustments. Using reliable equipment and taking accurate measurements can save large amounts of time.

Last, reset the thermostat to the proper room temperature. Instruct the owner on proper operation of the system. Record the information used in balancing the system, including the weather conditions on the day the job was balanced.

73.18 BALANCING A ZONED AIR SYSTEM INSTALLATION

The same procedure is used for balancing a zoned air system, except that zone dampers are adjusted to produce the correct airflow to each zone. The overall system airflow is established, the zone dampers are adjusted, and finally the dampers to individual runs are adjusted.

UNIT 73—SUMMARY

Testing and balance (TAB) procedures are the final check to confirm that the operation of a heating and air-conditioning system is within design specifications. A system that has not been tested and balanced can allow unhealthy conditions to develop in the conditioned space and could affect the long-term health of the occupants.

TAB is considered the first step in improving energy efficiency of an air-conditioning system.

TAB procedures are designed to balance airflow evenly in a structure, and this includes comparing design plans to actual measurements of duct system CFM along with all factors contributing to duct system CFM.

In addition to standard tools used by service technicians, TAB technicians may also use a chronometric tachometer, digital or analog capture hood, air-differential pressure gauges, and recording thermometers to perform their work.

The TAB industry is supported by many organizations and associations that produce standards and certifications for contractors and technicians as well as publications for consumer information.

WORK ORDERS

The service tickets are all on a small, single-zone commercial air-conditioning system with ducted return and supply air having the following specifications:

Design airflow: 4,000 CFM

Blower design pressure drop: 0.7 in wc

Design supply-air static pressure: 0.5 in wc

Design return-air static pressure: -0.2 in wc

Blower full load amp rating: 5.5 A

Service Ticket 7301

The technician measures the following system performance data:

Actual pressure drop across blower: 0.68 in wc

Measured airflow at blower: 4,050 CFM

Actual measured blower amp draw: 5.5 A

Total airflow at supply registers: 3,900 CFM

Total airflow at return grilles: 3,000 CFM

From this data, the technician concludes that the total airflow is within specifications but that the return-air duct has one or more leaks.

Service Ticket 7302

The technician measures the following system performance data:

Actual pressure drop across blower: 1.2 in wc

Actual measured supply-air static: 0.3 in wc

Actual measured return-air static: -0.9 in wc

Measured airflow at blower: 3,100 CFM

Actual measured blower amp draw: 2.5 A

From this data the technician determines that the overall airflow is low due to airflow restrictions that are causing an excessive pressure drop across the blower and reducing the airflow. The technician examines the supply- and return-air static pressure readings and notices that the return-air duct has a lower than normal static pressure reading. Static pressure readings across the HEPA filters show that the majority of the pressure drop is occurring at the filter. The filters appear clean. The technician looks up the application data for the filters. They are designed to have a static pressure drop of 1 in wc at their rated airflow. The technician informs the company that the filters will not work with the system.

Service Ticket 7303

The technician measures the following system performance data:

Actual pressure drop across blower: 0.5 in wc

Actual measured supply-air static: 0.3 in wc

Actual measured return-air static: -0.2 in wc

Measured airflow at blower: 3,000 CFM

Actual measured blower amp draw: 2.4 A

The technician notices that the pressure drop across the blower is lower than the design specification and that both the supply and return static pressures are lower than design. From this data the technician concludes that the blower speed should be increased to increase the system airflow.

UNIT 73—REVIEW QUESTIONS

1. List six types of measurements used to perform TAB procedures.
2. List five instruments used in TAB procedures.
3. Outline the general TAB procedure for system airflow.
4. Explain how to measure temperature rise.
5. Why is the temperature difference across an air-conditioning coil not used to calculate airflow?
6. Explain how to measure airflow using temperature rise.
7. How do the TAB procedures for a zoned system differ from a nonzoned system?
8. How is the CFM at a supply register determined using a velometer?
9. What does amp draw have to do with TAB procedures?
10. Why are the dampers on registers normally not used for balancing the system airflow?
11. Can a proper balance be performed on a duct system that does not have balancing dampers for each branch?
12. What can cause the total airflow leaving the supply registers to be much lower than the amount of air the blower is moving?
13. Why does a technician working for a TAB firm require specialized training?
14. How can TAB improve the health of the occupants?
15. Why is interest in TAB picking up in the residential market?
16. Can energy costs be affected by TAB of a system?
17. How are feet per minute measurements (fpm) different from cubic feet per minute measurements (CFM)?
18. Name two organizations that support the TAB industry by developing standards and offering certification.
19. How is a single pressure gauge with a rotating dial used to measure the pressure difference in a circulating water system?
20. Why would having a system tested and balanced be a good first step toward reducing energy cost?

UNIT 74

Commercial Air-Conditioning Systems

OBJECTIVES

After completing this unit, you will be able to:

1. explain the differences between residential, commercial, and industrial air-conditioning applications.
2. list the different types of commercial air-conditioning applications.
2. identify which type of equipment configuration best suits each commercial application.
4. list the basic chilled-water system compressor and condenser types.
5. describe the differences between single packaged conditioners and rooftop units.
6. describe the general arrangement of a direct expansion coil in an air-handling unit.
7. list the different types of heating and cooling coils.
8. select the proper coil for a given application.

74.1 INTRODUCTION

Air-conditioning systems may vary widely depending on the size of the space to be conditioned, the geographical location, and specific applications required for the space. For example, a hospital operating room demands reduced room temperatures along with highly filtered dry air. The requirements for such a system are far different from a hotel room that requires only minor levels of filtration along with the ability to supply both heating and cooling through simple operation.

Most systems utilize the standard mechanical refrigeration cycle components of compressors, condenser, flow control, and evaporator, but the physical size and location of the components will differ. In addition, the air-distribution systems for smaller units can be very simple by means of only a self-contained fan, while larger systems could have a complex layout of ducting that may include an economizer or dehumidifier function.

A large building in a dry, hot climate such as Arizona may be designed with an economizer that will use some outside air for cooling, particularly when the temperature begins to drop in the early evening. A supermarket in the Northeast may use a heat-reclaiming system to recirculate some of the heat removed by the condenser back into the store during the cold winter months. The air-conditioning system for the control room of a power plant is designed to keep the computer systems dry and cool, and therefore human comfort is only secondary to the needs of the equipment.

74.2 AIR-CONDITIONING APPLICATIONS

The type of air-conditioning system installed will depend on the geographical location, the size of the building, and the occupant use. There are many types of systems and designs, but they can generally be classified as being residential, commercial, or industrial.

Residential Air-Conditioning Systems

This category generally includes single-family, multifamily, and low-rise multifamily private household residences. The air-conditioning type is typically central forced air, central hydronic, or zoned. The capacities of residential installations typically range from less than 1 ton up to about 5 tons.

Commercial Air-Conditioning Systems

The commercial sector is generally defined as nonmanufacturing business establishments, including hotels, motels, restaurants, wholesale businesses, retail stores, and health, social, and educational institutions. The air-conditioning type varies considerably depending on the application. Systems can be as simple as a standard console through-the-wall conditioner for a hotel room. For conditioning multiple rooms or spaces in one building, single packaged conditioners, split-system conditioners, and rooftop conditioners are most commonly used. Many of the smaller systems ranging from fractional-tonnage room coolers up to about 20 to 30 tons are often referred to as “light commercial” systems (Figure 74-1). For substantial cooling loads,

Figure 74-1 Commercial rooftop single packaged unit.

large central forced air systems and chiller systems with ratings of 100 tons and above may be required.

Industrial Air-Conditioning Systems

Both residential and commercial air-conditioning systems are designed primarily for comfort. Industrial air-conditioning systems are designed for processes and environmental conditions that may require greater levels of filtration, more stringent humidity control, and special requirements for treatment of airborne contaminants that may result from a manufacturing process. Some examples of industrial facilities include laboratories, printing plants, textile processing plants, environmental control for animals and plants, wood and paper product facilities, nuclear facilities, and mine air-conditioning and ventilation. Many of the system types are similar in arrangement and equipment requirements as compared to large commercial systems.

74.3 COMMERCIAL AIR-CONDITIONING APPLICATIONS

There are many different types of commercial air-conditioning systems because there are such a wide range of establishments. For example, a system designed for a hotel or motel may be very different from one that would be found in a movie theater. There are many different commercial applications, including restaurants, shopping malls, hospitals, and train stations, just to name a few.

Hotels, Motels, and Dormitories

Very often each room will have its own unitary system, such as a through-the-wall packaged terminal air conditioner (PTAC) for heating and cooling. This type of unit is generally simple to operate and can be turned down or shut off since the room is not occupied at all times. The typical system consists of an indoor and outdoor coil, compressor, and refrigerant flow control. Electric heat is used either as a primary source or as an auxiliary source in the case of a heat pump application.

For larger areas where a single PTAC cannot meet the load requirements, single packaged vertical and horizontal units are typically installed. A horizontal unit can come as one complete assembly, however the air cooled condenser section must be placed outside. If that is a problem, then a mini-split system may be preferable. In this case, the compressor and condenser are located outdoors, thereby saving some inside space and reducing noise inside the building. These are also popular in residential applications and are described in Unit 44.

Restaurants, Nightclubs, and Casinos

Small cafeterias and bars with loads up to 10 tons will typically use direct expansion, self-contained packaged units located within the space itself. Large establishments will use some form of central plant with either forced air or a chilled-water system. These spaces require high ventilation rates to exhaust odors and fumes, which will require increased amounts of outside air. The increased air supply, however, should be admitted to the space without causing

drafts for people who are dining. The considerable latent heat load from cooking, food, and people who may be active or dancing requires a system with an increased cooling coil size to remove the excess moisture from the air. Special consideration needs to be given to odors. As an example, air should circulate from the dining area into the kitchen. This will keep odors out of the dining areas and serve to help the kitchen cool. Ideally, larger commercial kitchens should have a HVAC system separate from the dining area.

Supermarkets, Department Stores, and Malls

Supermarket systems are covered in detail in Unit 86. Department stores today are offering a number of conveniences, including supermarket areas, lunch counters, auto service areas, and garden shops. This variety of merchandise will affect the air-conditioning system type and requirements. Special ventilation requirements may be necessary if forklift trucks are entering the space. Major considerations to be taken into account for department store air-conditioning systems are the installation cost, floor space requirements, and simplicity of control. For these reasons, rooftop-mounted units are most commonly used. Usually the controls are operated by personnel who have little knowledge of air-conditioning systems, so they should be simple and fully automatic.

Malls often utilize a central plant to distribute chilled air for the enclosed mall and then to the individual tenant stores. Variable volume control of the air supply and electric reheat is used for the temperature control of each individual space or store. Generally the enclosed mall will be at a slight positive air pressure relative to atmospheric. Individual stores will maintain an air pressure that is best suited for their use. As an example, a store may operate under a negative pressure for better odor control.

Office Buildings

The variety of office building configurations allows for the use of almost every type of available air-conditioning system. A large office building will have some offices located near windows around the outer walls of the building, while others will be located on the interior of the building. The outer office's cooling load may vary considerably during the day as the sun rises and as the seasons change. The interior office's load will remain more uniform. Another consideration is the occupancy. Most office buildings are occupied from 8 AM until 6 PM. Lighting is also a consideration, as it is a significant part of the cooling load.

Small one-story office buildings may have individual unitary packaged systems for individual spaces. Multiple-story buildings may use forced air with a rooftop central unit. This could be a rooftop forced-air system or an air-cooled chiller as shown in Figure 74-2. Very large multistory office buildings often use a large central chilled-water system located in a mechanical equipment room (Figure 74-3). Each floor will have its own fan room where the chilled water supplied from the central system is used to indirectly cool the air. One mechanical equipment room usually services eight to twenty floors. The fewer the floors served by an equipment room, the greater the flexibility in controlling

Figure 74-2 Air-cooled chiller.

the space temperatures. One equipment room per floor will allow for better control, but there will be more units that require maintenance and increased installation costs. There may be some savings in efficiency because equipment can be shut off in unoccupied areas.

Hospitals and Nursing Homes

Of all the commercial areas, hospital air conditioning is the most demanding in terms of the overall requirements necessary. For these systems, the air-handling system can be very complex and sophisticated. Air circulation between spaces is often restricted. This is because many bacterial and viral infections, such as Legionnaires' disease or chicken pox, can be transported within the air. A good source of outside air will help to dilute viral and bacterial contaminants within a hospital. Special requirements for high-efficiency filters must be followed to make sure that the correct filters are installed and then replaced at regular intervals.

Temperature and humidity are of extreme concern for patient healing and recovery. Dry conditions can contribute to secondary infection and should be avoided. However, an increased relative humidity is not necessarily desired, as some bacteria survive more readily in a humid environment. Therefore, general clinic areas of the entire hospital

Figure 74-3 Semihermetic centrifugal water-cooled chiller.

are typically maintained at 30–60 percent relative humidity. However, individual operating rooms, delivery rooms, recovery rooms, intensive care units, and all other special treatment spaces will all have varying requirements that must be maintained.

Most hospitals will have a fairly large hot-water central heating system utilizing steam boilers. Steam is also used for the sterilization of utensils, instruments, and equipment. Large centrifugal or screw-type compressors are often used for the chilled-water cooling plant. Most hospitals have backup emergency power in the event that the local power is disrupted. This backup power may be supplied by gasoline or diesel-powered generators. Some of the newest systems use the combined cycle of gas and steam turbine-driven generators. The gas turbine exhaust passes through a heat exchanger to boil water and produce steam. This steam, which is generated from heat that would normally be lost up the stack, is supplied to the steam turbine-driven generator. Because there is an abundance of heat in this type of system, absorption-type chillers can be used to reduce total operating costs. An example would be a gas turbine-driven refrigeration compressor with the waste heat being used for an air-conditioning absorption system.

Nursing homes have many of the same requirements as hospitals in regard to air quality, temperature, and humidity. However, since normally there are few special treatment spaces, such as operating rooms, the overall demands for the system are far less complex. Individual room temperature control should be allowed for, and the registers should be located to reduce drafts. It is not uncommon for these systems to have large volumes of outside air admitted for odor control. To reduce operating costs, odor may be controlled with activated carbon or potassium permanganate-impregnated activated alumina filters.

Schools, Colleges, and Universities

The type of system normally found will vary depending whether the facility is new or existing and whether it is to be totally or partially renovated at some point. It should be a system that can be easily maintained by the institution's maintenance staff. Educational facilities typically have very limited budgets, so energy savings are often extremely important, and this can affect the type of system that is installed. Schools that need to grow with new additions or wings may not necessarily add new heating and cooling systems but instead may just upgrade and add on to the existing system.

There are a number of methods to reduce energy consumption that can be somewhat straightforward to incorporate. Outdoor economizer cycles use the cooler outdoor air whenever the outside air temperature begins to drop. This helps to offset the high inside load, which has increased during the peak load part of the day. Night set-back conserves energy by resetting the heating and cooling space temperatures during the evening hours when no one is in the building. Morning warmup and cool-down will reset the temperature back to normal with enough time allowed for the space to be comfortable when the students arrive at school.

The use of the facility is normally taken into account. As an example, a preschool should be configured to minimize

drafts near the floor level. This is because the children are small and will most likely be playing on the floor a majority of the time. Large universities will have multiple buildings that may each utilize its own central cooling system. Many schools in northern climates will not have any air-conditioning system at all. This is because during the summer months when it would be required, school is normally out of session. If summer sessions are held, windows are opened to provide for air circulation.

Airports, Bus Stations, Ship Docks, and Train Stations

These are generally large open areas one or more stories high. Heating and cooling is typically supplied from a central system through an air-distribution system that has multiple zones. Some problems encountered relate to the air balancing of the space due to the many outside openings, high ceilings, and long, low passageways. The requirements for these spaces are different from office buildings in that often transportation centers are occupied on a 24-hour-a-day basis.

Auditoriums, Movie Theaters, Arenas, and Stadiums

These spaces are subject to high peak loads during an event and then very reduced loads at most other times. Many events are held in the evening rather than at the peak load portion of the day, which helps to minimize the cooling demand. The major cooling load results from the people in the space, and relative humidity is a concern. Large systems will be designed to cool the air down below its dew point for the removal of moisture and then utilize some form of reheat. Often large central chilled-water systems are used for these facilities. The air supply would be too noisy if located near the seating area, particularly for a theater where a performance is being held. In most cases, air is supplied from overhead at a high enough velocity to reach the seating area without being too noisy. The return-air registers are located near the seats to help circulate the air through the space. Many auditoriums and arenas are designed to operate on all outside air, because during setup time trucks may be used to bring in equipment and supplies.

74.4 INDUSTRIAL AIR-CONDITIONING APPLICATIONS

Residential and commercial air-conditioning systems are generally designed for human comfort. Industrial systems are different, as more often the main purpose is to ensure product quality at a manufacturing facility. Air quality, temperature, and humidity can be critical in many manufacturing environments.

Manufacturing Plants

There are many different types of manufacturing facilities, and each has its own needs and requirements for air conditioning. Some typical applications include the

manufacture or processing of ceramics, plastics, leather, plywood, textiles, rubber dipped goods, floor coverings, and electrical products. Then there are consumer products such as tea, tobacco, and distilled liquors. Many applications require some form of painting process that requires special air-filtration systems.

These facilities often require the use of large amounts of energy for the manufacturing processes involved and also for the air-conditioning systems. Many processes require specific temperature and humidity levels. As an example, in the manufacture of rayon, temperature controls the rate of reaction and humidity maintains the solution at a constant strength. For varnish drying, the temperature is critical, and proper humidity levels reduce the formation of bubbles on the surface.

Moisture regain is important for the processing of hygroscopic materials such as textiles, paper, wood, leather, and tobacco. A hygroscopic material readily absorbs moisture from the air. Moisture regain is the percentage of absorbed moisture in a material as compared to its bone-dry mass. Conditioning and drying are the typical processes utilized for removing or adding hygroscopic and free moisture. These two are combined to accurately regulate the final moisture content in products such as textiles and tobacco. Large dryer drums are used for the papermaking process.

In the manufacturing process, many airborne particles may be released. Some of these include dust, bacteria, smoke, spores, pollen, and radioactive particles. If left unfiltered, these may spoil perishable goods and clog small openings in precision machinery. Static electricity can be dangerous in explosive atmospheres, and generally its effect is minimized at humidity levels above 35 percent.

The most important factor to be considered given all of these requirements is to also provide an environment that is suitable for employees working at the facility. High temperature and humidity levels can lead to worker fatigue. An employee who is sweating can leave fingerprints on finished metal products, and the salt and acid from perspiration can cause corrosion and rust on metal surfaces. Most of the workplace standards are set and enforced by the Occupational Safety and Health Administration (OSHA). Industrial manufacturing plants are usually designed for an internal temperature of 60°F to 90°F and a maximum of 60 percent relative humidity.

With the many different types of requirements and the many diverse industrial manufacturing processes, there is no one common air-conditioning system that is typically used. For large facilities, central systems generally are the most cost effective. Very often there will also be refrigeration systems and heating systems located within the plant that are required for the process. If there is a need for process heating with hot water or steam, then there may be waste heat available or conditions suited for a combined cycle application. Whenever this is the case, an absorption chiller system may prove to be the most cost effective. As an example, steam may be used for a drying process. Once the steam has been used for heating, it may need to be condensed back into water and then sent back to the boiler to be heated again. However, if there is still enough heat available in the steam to be used in an absorption chiller, this may be a better route. The steam condenses in the

absorption chiller, giving off its latent heat before traveling back to the boiler.

74.5 SINGLE PACKAGED CONDITIONERS

A single packaged conditioner, often called a Unitaire, is a complete self-contained factory-built unit, for permanent installation, to condition larger spaces than would be practical using single room conditioners. In this category there are two variations of available equipment:

- **Horizontal conditioner** Horizontal packaged heating and cooling units, with integral air cooled condensers, in the size range of 1½ to 5 tons
- **Vertical conditioner** Vertical self-contained air conditioners, with water-cooled or remote air-cooled condensers, in the size range of 3 to 15 tons

74.6 HORIZONTAL PACKAGE CONDITIONER

The horizontal unit usually uses ductwork for air distribution. The horizontal unit is completely self-contained, including the air-cooled condenser. It therefore must be placed either entirely outside or at least with the condenser section outside. A schematic diagram for the arrangement of parts is shown in Figure 74-4.

The unit is primarily a cooling unit, although electric heaters can be installed in the unit as shown in Figure 74-5. The unit can be equipped with supply- and return-air duct connections. Ducts can be entered from the side or bottom, depending on the application. The unit can be installed on the roof, as shown in Figure 74-6. This type of application is used for shopping malls, factories, and other commercial buildings.

Units range in capacity from 18,000 to 60,000 BTU/hr and range in air quantity from 600 to 2,000 CFM at standard rating conditions. All units are available for 208/230 V, single-phase, 60 Hz power. Efficiencies range from 10.0 EER and higher depending on the size. Optional electric heaters range in size from 3.74 to 29.80 kW.

The horizontal unit comes equipped with the following features:

Figure 74-4 Component arrangement for a single packaged conditioner.

(a)

(b)

Figure 74-5 (a) Electric heaters for a packaged air conditioner; (b) Nichrome resistance heating wire.

Figure 74-6 Roof installation of a single packaged air conditioner.

- **Water protection** A weather-resistant cabinet along with a water-shedding base pan with elevated downflow openings and a perimeter channel prevent water from draining into the ductwork.

- **Low ambient control (optional)** Kits are available that control the condenser head pressure to permit the unit to cool even at low ambient temperatures.
- **Economizer (optional)** An economizer and dry-bulb temperature sensor can be supplied for downflow installations. This makes it possible to use outside air for cooling when outdoor temperatures and humidity permit.
- **Enthalpy control kit (optional)** This can be supplied in place of the dry-bulb sensor, or two enthalpy controls can be paired to provide differential enthalpy control.
- **Fresh air (25 percent) kit (optional)** This kit can be mounted over the horizontal return-air openings for downflow requirements. It also can be used on horizontal applications by cutting a hole in the return-air duct or in the unit filter access panel.
- **Fan-delay relay kit (optional)** This control keeps the indoor blower on for about 90 seconds after the unit stops to improve the EER.
- **Anti-short cycle timer** A time-off device ensures a minimum of 5 minutes off between compressor cycles.

74.7 VERTICAL PACKAGED CONDITIONER

This is a packaged unit for installation, usually inside the space being conditioned. The condenser is water cooled. Water from a remotely located cooling tower needs to be piped in and out of a water-cooled condenser.

Discharge air can either be free throw or ducted horizontally or vertically. An accessory plenum and grille that fits on top of the unit is supplied for the free-throw arrangement. When ductwork is used, a number of discharge configurations can be supplied.

Application features that are incorporated into the unit are as follows:

- The evaporator fan speed is adjustable, affecting the air-delivery CFM and the available ductwork static pressure.
- Thermostats can be supplied as an integral part of the unit, or provision can be made for remote mounting.
- An anti-short-cycle timer is provided to protect the compressor from excess cycling.

74.8 ROOFTOP CONDITIONERS

Rooftop conditioners are similar to single packaged conditioners except that they are thoroughly weatherproofed and provide for duct access at the bottom of the unit. They are popular for air conditioning low-story commercial buildings because they offer a substantial savings of space within the building. They come in various sizes and configurations.

From the standpoint of the service technician, they are desirable because they offer plenty of access space around the unit for servicing. On many jobs, however, access to the roof is only by ladder, and in bad weather the units may be difficult to reach and offer physical restraints in supplying needed tools and parts.

SERVICE TIP

One of the prime concerns and problems with all rooftop installations is water leakage. Most commercial buildings use flat roofs, and water in a rainstorm can build up to several inches in depth. If the equipment panels are not properly reinstalled to provide an adequate water seal, rainwater can easily enter the building. In addition, if the proper curb is not provided for the unit, then the system will leak. Many commercial roofs are "bonded," which means that there is a specific insurance policy taken out on the roof by the roofing company at the time of installation. This provides the building owner with insurance that the roof will not leak. That roofing contractor is the only one who can do any work on the roof that would affect the integrity of that roof without violating that bond. Violating the bond on the roof by putting in a vent pipe could ultimately make you liable for any water damage resulting from leaks. Check with the building owner before any work is done on bonded roofs.

Rooftop self-contained air conditioning units are commonly used on commercial installations (Figure 74-7). The sizes range from 3 tons to 130 tons of cooling capacity under standard rating conditions. Besides the difference in size of the components, individual units differ in the type of heating supplied with the package.

For the units in the 3–25-ton range, gas-fired or electric heat can be supplied. Larger units can also be equipped with hot-water or steam coils. When the units are located outside, adequate freeze protection needs to be provided where the unit contains water. Condensate drain pans must be free draining.

Reciprocating or scroll-type, direct-drive, semihermetic, and hermetic compressors are used. Compressor motors are suction-gas cooled and are protected with temperature- and current-sensitive overloads. Crankcase heaters are standard equipment. Dual-compressor models are usually available starting at 7½ tons and higher. When dual compressors are furnished, dual-refrigeration circuits are also supplied. This arrangement makes possible better performance ratings and increased energy savings at partial loads.

Figure 74-7 Rooftop packaged system.

Cabinets are constructed of zinc-coated, heavy-gauge steel and are weather tight. All services can be performed through access panels on one side. Supply and return duct-work connections can be made at the bottom or side of the unit. Roof curb frames are available for roof mounting.

74.9 CENTRAL SYSTEM CHILLERS

For large air-conditioning loads, central systems utilizing chilled water are often used. There are many different configurations that can range from capacities of more than 700 tons for large absorption systems to as little as 15 tons for small reciprocating chillers.

Chilled-water systems can utilize reciprocating, centrifugal, and screw-type compressors. These can be configured as open or semihermetic systems. Condensers are often water cooled, and if no ready source of water is available, then cooling water towers are used. Chillers can also come as air-cooled units, but the compressor location is then limited. The compressor needs to be located relatively close to the condenser. With a water-cooled unit, the compressor can be located most anywhere with the condenser water pumped to its location.

Chillers can also be configured as absorption systems. A major advantage is that no compressor is required. Another advantage of this type is that waste heat can be utilized as the driving heat source, which provides for economical operation.

74.10 AIR-HANDLING UNITS

A small residential horizontal air handler would have a direct expansion (DX) coil and a blower as shown in Figure 74-8. This would be a fairly simple type of air handler to install and service. Larger air handlers are more complex. In large air-handling systems, the chiller supplies chilled water to the cooling coil located in the air-handler assembly. This cooling circuit consists of a chiller, a pump, the cooling coil, and all necessary piping. Separate from the air handler, the compressor for the chiller system utilizes a water-cooled condenser.

Figure 74-8 Cooling-only horizontal flow air-handler with DX coil.

The condenser-cooling water circuit consists of a cooling tower, a pump, and a water-cooled condenser (part of the chiller). This is actually a subcircuit to the cooling circuit. This type of configuration will also have a heating circuit that generally consists of the boiler, a pump, and the heating coil.

SERVICE TIP

A common maintenance task is the replacement of the filters at the inlet of the air handler chilled/heat coil. A building may have large and small air-handler units (all usually located in relatively inaccessible locations and environments) with different filter demands. It is important to make sure that filters are changed when needed and not overlooked.

74.11 DIRECT EXPANSION (DX) COILS

Many residential and light commercial air handlers will have DX coils (Figure 74-9). These may come from the factory without refrigerant and pressurized with nitrogen. If this is the case, they should be checked for pressure with the installed Schrader valve prior to installation. If no pressure

Figure 74-9 DX coils for air-handler applications.

is present, then the coil may have developed a leak during shipment and should be returned. Before installation, all of the nitrogen should be released and the ends of the connections cut off.

SAFETY TIP

Make sure to bleed all the pressure from the DX coil before cutting off the end caps. Also make sure to protect your eyes and face while doing so.

Once the connections have been cut off (Figure 74-10), they should be prepared for flaring or brazing. A liquid-line filter drier should be installed as close to the coil as possible. When brazing a thermostatic expansion valve (TEV), always direct the flame away from the valve body. As an added precaution, a wet cloth should be wrapped around the body and element during the brazing operation (Figure 74-11). After the proper fittings have been soldered, the TEV can be installed. If the TEV is externally equalized, run both the temperature-sensing and pressure-sensing lines to the coil outlet (Figure 74-12).

Figure 74-10 Connection after the end has been cut off.

Figure 74-11 Wrap a wet cloth around the valve body when brazing.

Figure 74-12 Properly locate and install both the temperature-sensing and pressure-sensing lines.

Make sure that the TEV temperature-sensing bulb is attached to the coil and properly insulated. The sensing bulb can be installed in a vertical or horizontal position, as shown previously in Figure 74-9. The external equalizing connection is typically used on large evaporator sizes and should be located close to and downstream of the sensing bulb. On horizontal runs, the connection should be made to the top of the tube. On vertical runs, the connection should be made well above the beginning of the riser. Some DX coils have an oil-return connection at the bottom of the suction header, as shown previously in Figure 74-9. This is a small-diameter line that will return oil to the compressor.

Staging and Hot Gas Bypass

Generally some type of staging control system is used. With a change in load demand, the compressor may be staged to start or stop. A liquid-line solenoid valve can be used for capacity control. Another type of staging is unloading. Rather than allowing the compressor to continually cycle with demand, unloaders are often used to cut out individual compressor cylinders or banks of cylinders (Figure 74-13).

Figure 74-13 Compressor unloader solenoid.

Often two compressors are staged together. As an example, at maximum demand, both compressors operate at full load. As the demand drops, the lag compressor begins unloading cylinders. As demand drops further, the lag compressor shuts down and only the lead compressor remains in operation. If the demand drops even further, then the lead compressor begins to unload cylinders.

Larger light commercial systems may require hot gas bypass for low load operation. The hot gas is introduced between the expansion valve and the distributor.

74.12 CHILLED-WATER COOLING COILS

Chilled-water systems are referred to as indirect expansion systems. A primary refrigerant will be used to remove heat from a secondary refrigerant in a chiller unit. The primary refrigerant remains in the chiller unit and operates on the normal refrigeration cycle. The secondary refrigerant (chilled water) will be pumped to the air-handler cooling coils and then return to the chiller. An example of a chiller is shown in Figure 74-14.

The secondary refrigerant does not change state and expand when it removes heat from the air, and so this type of system is known as indirect expansion. The secondary refrigerant is often a glycol and water mixture. The water should be of high quality, preferably distilled water, to avoid the buildup of scale on the inside tubing

surfaces due to mineral deposits and sediments contained within the water. The glycol (antifreeze) will help to prevent freezing of the cooling coil if the outside air temperature drops too low. Coil-freeze-up thermostats can be installed to shut down the system if the air temperature drops below 36°F. Thermostats can also measure water coil temperature to shut the unit down if it gets to or near the freezing point. For cold weather winter conditions, it is recommended that the coil be drained of water and flushed with antifreeze.

TECH TIP

In addition to protecting the cooling coil from freezing, glycol solutions generally have corrosion inhibitors added. These will protect the interior of the cooling coils and associated piping from prematurely rusting away. One drawback of glycol is that its specific heat is lower than that of water so it does not transfer heat as well.

Chilled-water cooling coils are generally installed for counterflow. They should be piped so that the coldest water meets the coldest air. After installation, chilled-water coils need to be purged of air through the bleed valve (vent).

74.13 HOT-WATER COILS

Air handlers can be configured with both cooling and heating coils (Figure 74-15). The heating coil is located in the airstream before the cooling coil. This arrangement will help to reduce the possibility of the cooling coil freezing during cold weather conditions. Steam heating coils are more efficient than hot-water heating coils, but boilers that generate steam fall under stricter regulation and require more safety controls. Therefore, many heating systems for residential and light commercial applications use circulated hot water rather than steam.

The hot water for the heating coil is normally supplied from a boiler and will circulate from the boiler to the air handler and back again. This type of heating coil will have a bleed valve (Figure 74-16). Hot water coils should be piped for counterflow so that the warmest water meets the warmest air. The hot-water loop will include an expansion tank and a fill connection. Similar to a cooling coil, high-quality distilled water should be used for the circulated hot water to prevent scale formation on the inside of the coil surfaces.

74.14 STEAM HEATING COILS

Steam heating coils will be smaller in physical size than a comparable hot-water heating coil. This is because the coil not only transfers the sensible heat of the steam to the air but also the latent heat as the steam changes back to water within the heating coil. A steam trap is located at the outlet of the heating coil. To gain the most efficiency, it is

Figure 74-14 Large commercial chiller unit.

important that the steam turn back to water, thereby giving up as much heat as possible before leaving the heating coil. The water formed from the steam condensing inside the heating coil is commonly referred to as condensate. The condensate will return to the boiler and be heated again to turn back into steam.

The water quality for this type of system is even more important than a chilled-water or hot-water loop. Since the water is boiling in the furnace, there is an even greater tendency for minerals and deposits to come out of the water

Figure 74-15 Horizontal flow configuration with heating and cooling coils.

Figure 74-16 Hot-water coil with bleed vent.

and collect on the boiler heat-transfer surfaces. It is essential that only high-quality distilled water be used for this type of system.

SAFETY TIP

When working on a steam coil or steam trap, always make sure that the steam supply is shut off. Wear heavy gloves and a long-sleeve shirt whenever disconnecting steam line components. Always bleed off any pressure in the line before opening or disconnecting components.

An advantage to a steam system is that circulating pumps are not required. In a hot-water system, pumps must run to circulate the hot water to the heating coil and then back to the furnace. For steam systems, supply pumps are not required. The steam under pressure will travel through the piping and into the heating coil. The condensate leaves the heating coil through a steam trap. This is generally piped as a gravity or vacuum return to a condensate return tank (Figure 74-17). The condensate from the drain tank will be drawn off as feed water for the boiler by a feed water pump.

TECH TIP

Steam traps will generally have a bypass valve around them. If a steam trap happens to freeze in a stuck-closed position, the steam flow through the coil will stop. The bypass valve can be opened to bring the coil temperature back up to normal and the trap can be isolated and replaced.

Figure 74-18 Standard finned-coil construction.

74.15 COIL CLEANING AND CORROSION

Chilled water, hot water, steam, and DX coil exterior surfaces must be cleaned regularly. The exterior surfaces of the coils are often finned to help increase the heat-transfer surface area (Figure 74-18). The finned coils provide an opportunity for dirt and grime to collect. Dirty coils reduce heat transfer and lead to increased operating costs due to inefficiency. On direct expansion systems, a dirty coil can lead to liquid floodback and compressor slugging.

Water that forms and collects on the coil surface will drip off and fall into the drain pan located beneath the coil. Dirt and grease collecting on the fins and coil reduce the wettability of the coil surface. Rather than collecting on the coil and dripping into the drain pan, the water will be moved through the system with the air to potentially create moisture problems in other areas of the air-distribution system. Surface grime and wet conditions can also lead to microbial growth (mold), which leads to foul odors and health-related indoor air-quality problems. Coils can be pressure cleaned with hot water and detergent or a commercial coil cleaner.

Figure 74-17 Steam coil supply and return.

TECH TIP

Some chemical cleaning solutions are self-rinsing, and over time the solution will be rinsed by the condensate and the coil will not be harmed. However, if a standard chemical cleaning solution is used when cleaning the coil exterior surfaces, always make sure to rinse the coil surface thoroughly after the cleaning is complete.

Coil Corrosion

Corrosion can be caused by chemical, physical, or electrochemical reaction due to exposure from elements in the environment. Coils located in coastal and marine areas are subject to corrosion from sodium chloride (salt) that is carried by sea spray, mist, or fog. Units located near industrial areas may be exposed to corrosive emissions such as sulfur oxides (SO_2 and SO_3) and nitrogen oxides (NO_2), which lead to the formation of acid rain. In addition, dust particles containing harmful metal oxides, chlorides, sulfates, sulfuric acid, carbon, and carbon compounds may also be prevalent. Coils located in urban areas are susceptible to high sulfur oxide and nitrogen oxide levels generated from automobile and heating emissions.

The two common types of coil corrosion are galvanic and general corrosion. Galvanic corrosion occurs when two dissimilar metals are in contact with one another and an electrolyte is present. A coil with copper tubes and aluminum fins will be subject to galvanic corrosion in the pres-

ence of sodium or calcium chloride compounds. These are most commonly found in sea spray near coastal areas. Aluminum is a less noble metal than copper and so the fins will begin to deteriorate first.

General corrosion is caused by oxidation and chemical attack on the coil tubing surfaces. As an example, copper is susceptible to attack from gases containing sulfur. This leads to general corrosion that consumes some of the copper to form metal oxides on the tube surface. Eventually the copper tubing becomes thinner and thinner and turns brittle, resulting in tube failure (Figure 74-19).

There are a number of processes that can be applied to coils to reduce the potential for corrosion. Aluminum fin coils can be precoated with a durable epoxy coating for mildly corrosive environments. Aluminum fins may also be electrocoated through a multistep process that ensures the ultraclean coils are properly coated and cured. To reduce the chance of galvanic corrosion resulting from the use of dissimilar metals, copper fins rather than aluminum are mechanically bonded to copper tubes. A disadvantage, however, is that this type of coil can be rather expensive in comparison to standard aluminum fins. Refer to manufacturers' supply information to help determine which type of coil is best suited for any particular application.

Figure 74-19 Coil tubing failure due to general corrosion.

UNIT 74—SUMMARY

In this unit you have learned about different types of air-conditioning systems, such as console-type through-the-wall conditioners, single packaged conditioners, rooftop conditioners, and chillers. Unitary equipment is factory built to be as complete as possible and fairly simple to install.

Packaged terminal air conditioners (PTAC) are most commonly used in hotels, nursing homes, and apartment complexes. Single packaged conditioners can be of the horizontal or vertical type and are permanently located in a separate space away from the room being cooled. Ductwork is often used for air distribution, and horizontal units are generally sized from 1½ to 5 tons, while vertical units range from 3 to 15 tons.

Rooftop conditioners are similar to single packaged conditioners except that they are thoroughly waterproofed. In this way they can be conveniently located on the building's roof, thus conserving valuable inside building space. Large air-conditioning load capacities often require chillers, which can operate with mechanical compressors or as absorption-type systems.

Air handlers come in many varied configurations and sizes. Many commercial and light commercial handlers are available in sectional units that can be put together like building blocks to meet the requirements for a specific application. All air handlers will have a fan and cooling/heating coils. However, the fan size, speed, and type of control will vary depending on the space requirements. There are also different types of coils. These can be direct expansion, chilled water, hot water, or steam type.

WORK ORDERS

Service Ticket 7401

Building Conversion: New Installation

Equipment Type: Rooftop Packaged Unit/PTAC

The company sales representative visits with the owner of a small business who is in the process of converting an older one-story building into office spaces. The old air-distribution system is to be entirely replaced. The owner is wondering if through-the-wall individual packaged terminal units for each space will be sufficient.

The sales representative uses information about the building dimensions, construction materials, and outside/inside design temperatures to determine the total heating and cooling load for the building. He then explains to the owner that a PTAC for each space would be sufficient to handle the load. Some advantages to the PTACs are that they can be turned down anytime someone is not in that particular office space, and no new duct system needs to be installed during the building conversion. However, the inner offices would require mini-split systems rather than using through-the-wall units.

Although a packaged rooftop unit would involve the installation of an air-distribution system, this would be the best time to do that, while the building interior is being torn apart. The salesman recommends a cooling/heating rooftop unit with a gas furnace. This would prove much more economical over time for heating as compared to the electric resistance heat of a PTAC. The initial cost would be higher and the control system somewhat more complex, but the overall comfort for both the heating and cooling season would be better. The PTACs also could be noisy for the office space, so the owner decides on installing the rooftop packaged unit.

Service Ticket 7402

Customer Complaint: Cold Conference Room

Equipment Type: Central Chilled-Water System

The technician answers a call at a large office building downtown. There is a problem with the cooling system in the conference room on the sixth floor. The 120-ton semihermetic centrifugal chiller located in a machinery room in the basement is operating normally. Everything also appears normal in the sixth floor fan room, with the chilled-water supply temperature at 45°F and the return at 55°F.

When the service technician enters the conference room, it immediately feels cold. The supply register has cardboard taped over it, and air is whistling through the cracks. The technician uses a small stepladder and removes the ceiling panels from around the supply register. This system has steam reheat, and the steam coil is now exposed. Without any reheat, cold air is

being supplied regardless of the setting on the space thermostat. The supply damper is fixed in place and reheat is the only adjustment for space temperature. The technician finds that the steam-regulating supply valve to the reheater is frozen shut. The steam supply to the line is secured and the valve replaced. Soon after, the space temperature starts returning to a more comfortable level.

Service Ticket 7403

New Installation: System Replacement

Equipment Type: Packaged Rooftop Unit

The service technician arrives at the job site and finds that the new packaged rooftop unit has already been lifted on to the roof of the building. Climbing up the fire escape to where the unit is located, the technician brings along a tape measure and the installation specifications for the new unit. Before even beginning to make measurements, it is obvious that the footprint for the new unit is going to be quite a bit larger than the old unit. There are also structural members that will need to be reinforced for the rooftop foundation.

The service technician goes back down and locates the building superintendent. The roof is "bonded," and any new penetrations need to be approved by the roofing contractor. The technician arranges for the installation to begin in coordination with a crew from the roofing company. They need to work together to make sure that the old unit is properly removed and the new unit installed with adequate support.

UNIT 74—REVIEW QUESTIONS

1. Define *residential air conditioning*.
2. List at least five types commercial air-conditioning applications.
3. If a direct expansion coil delivered from the factory has lost its nitrogen pressure charge, what should be done?
4. How should an external equalizing line for a TEV be connected to a horizontal run?
5. List the different types of staging that can be used for air-handler compressors using direct expansion coils.
6. What is the difference between a primary and a secondary refrigerant?
7. What is a special ventilation consideration for restaurants, nightclubs, and casinos?
8. What type of water should be used in a chilled-water system?
9. What consideration should be given to office spaces when determining space heating and cooling loads?
10. State the two variations of single packaged conditioners and the tonnage capacity ranges of each.
11. The single packaged conditioner in the horizontal variation may come equipped with seven features. What are these?
12. What are the differences between a rooftop air conditioner and a single packaged air conditioner?

13. Why are rooftop units popular on small commercial buildings?
14. Explain what would happen if an HVACR contractor violated a bonded roof by putting in a vent pipe.
15. Could a packaged rooftop unit be adapted for both heating and cooling?
16. How are hermetic compressors cooled?
17. What types of compressors are commonly used for chillers?
18. Why do many central system chillers use water-cooled condensers?
19. What is moisture regain?
20. List some of the airborne particles that may be released in an industrial manufacturing process.
22. How should hot-water heating coils be piped?
23. What happens if the steam trap at the outlet of a heating coil is stuck in the closed position?
24. Should heating and cooling coil exterior surfaces ever be cleaned?
25. What are the two common types of coil corrosion?
26. What happens when metal oxides are formed on the coil tube surfaces?
27. What is galvanic corrosion?

UNIT 75

Fans and Air-Handling Units

OBJECTIVES

After completing this unit, you will be able to:

1. describe the different types of air handlers.
2. explain the operation of a fan coil unit.
3. list the different types of coils used for heating and cooling.
4. identify types of fans and describe their uses.
5. explain the differences between centrifugal and axial fan arrangements.
6. use the fan laws to predict the end result of changing fan speed, air volume, static pressure difference, or fan horsepower.
7. use a fan curve to predict fan performance.
8. list the different types of air filters used in air handlers.
9. explain how humidifiers operate.
10. describe the operation of economizers and energy-recovery ventilation sections.

75.1 INTRODUCTION

Air conditioning involves more than just cooling or heating air. The air also needs to be filtered, humidified or dehumidified, and distributed to the proper location in the appropriate amount at the designed velocity. Too little outside air will lead to an increase in the level of indoor pollutants. Too much outside air increases the load on the system and leads to lower efficiencies and higher operating costs. Air balance is important so that doors inside a building open easily and close without slamming shut. Too little exhaust air can lead to overpressurization of a space.

The air-handler unit (AHU) should be selected and installed with all of the major requirements for the space taken into account. These include the air handler's location, type of coil design, and filtration ability. A central station AHU may offer economy of operation as compared to individual space fan coil units. However, individual units may provide for better temperature control and eliminate the mixing of airstreams between rooms, such as may be required in a laboratory or hospital. Individual fan coil units can also be shut down when the space is unoccupied, such as in a hotel room. The decision to install one large central air handler, multiple air handlers, or individual fan coil units requires careful planning and consideration of the building's main functions and requirements.

75.2 TYPES OF AIR-HANDLING UNITS

AHUs come in various sizes and configurations. These can be arranged as complete packaged systems for residential, light, and moderate commercial applications. Large central-air-conditioning systems typically have built-up units that are assembled component by component. Sometimes these come as modular building blocks and can be arranged in a variety of configurations (Figure 75-1). Depending on the application, the air handler may be located in the conditioned area. However, installation in the basement, on a rooftop, or in some other isolated area saves on valuable inside space and reduces the fan noise heard by the

people indoors. Figure 75-2 shows the proper installation for ceiling-mounted units that may be found in a large retail store or in warehouse applications. Many of these units have double-wall insulation, which reduces sweating on the outside surfaces and noise from the fan compartment.

The location for the air handler is usually flexible because it does not need to be located alongside the heating and cooling equipment. The handler can be as simple as a fan, a filter, and a coil. For example, a residential split system has refrigerant supplied from the outdoor unit to an air handler that may be located in the basement. This type of system would require just the basic components and would be considered a direct expansion system. However, for larger buildings that require more than one air handler, it would be impractical to deliver refrigerant to each one. In this case, a central plant will cool a secondary refrigerant (chilled water) that is then delivered to each air-handler coil. This type of air handler may also have additional hot-water or steam coils for heating and mixing and dampers for energy-recovery applications. Figure 75-3 shows a large indoor air handler.

Figure 75-1 Modular air-distribution components.

Figure 75-2 Ceiling-mounted air handler.

Figure 75-3 Indoor air handlers.

Most air handlers use a fan (or blower) to force the air at low, medium, or high velocity through the air-distribution system. Draw-through units are designed so that the fan is at the outlet of the air handler to draw the air across the coils (Figure 75-4). This is more common than a blow-through type where the fan is located at the inlet to the coils. Sometimes blow-through systems can be used if sound levels are a major consideration. Noise levels can be lowered because sound is absorbed by the coil section downstream from the fan. Less common are induction units that are designed to operate without any fan.

Air handlers can be designed to deliver a constant volume or a variable volume of air to a single zone or to multiple zones. A constant-volume system always supplies the same amount of air, and to control the temperature of the space, the supply-air temperature has to be regulated. In contrast, a variable-volume system will adjust to supply

Figure 75-4 Draw-through horizontal air handler.

more or less air depending on the space temperature. In this case, the supply-air temperature does not need to change.

75.3 FAN COIL UNITS

Fan coil units (FCUs) are supplied with chilled water directly from a central plant and can also include heating coils or electric heat. They are primarily designed to supply conditioned air to individual rooms, but larger FCUs are capable of conditioning multiple spaces. Each one of these units has fans, cooling coils, filters, a fresh air supply, and a control system.

FCUs for combination heating and cooling come in a variety of designs, to fit under windowsills, above furred ceilings, and in vertical supports built into walls. FCUs have many of the same advantages of packaged terminal air conditioners (PTACs). These include individual space temperature controls and no requirements for a large duct system. However, unlike packaged air conditioners, the efficiency of a central plant can be realized. An indoor water-cooled condensing unit or split-system outdoor condenser is not needed. All that is required is an insulated chilled-water loop piped from the central plant chiller.

FCUs have a wide variety of applications. One advantage is the ability to provide individual room conditioning. This is desirable in applications for hospital rooms, motel rooms, and individual private offices. An accessory fresh-air duct can be provided in the bottom rear of the unit to permit the entrance of outside ventilation air. Each room unit can be individually controlled without mixing air from an adjacent room.

A common type of FCU, the individual room conditioner, is shown in Figure 75-5. This type of unit consists of a filter, direct-driven centrifugal fan(s), and a coil suitable for handling chilled or hot water. The size of the unit is based on its cooling ability; it is usually more than adequate for heating. A variety of water-flow control packages are available for manual, semiautomatic, or fully automatic motorized or solenoid valve operation.

TECH TIP

Often around fluorescent lights in a dropped ceiling there is a narrow slit. That opening is the return air. In this location the heat generated by the light is drawn into the return airstream, allowing for less heat to be radiated into the occupied space. The high artificial light levels in most commercial buildings represent a significant cooling load.

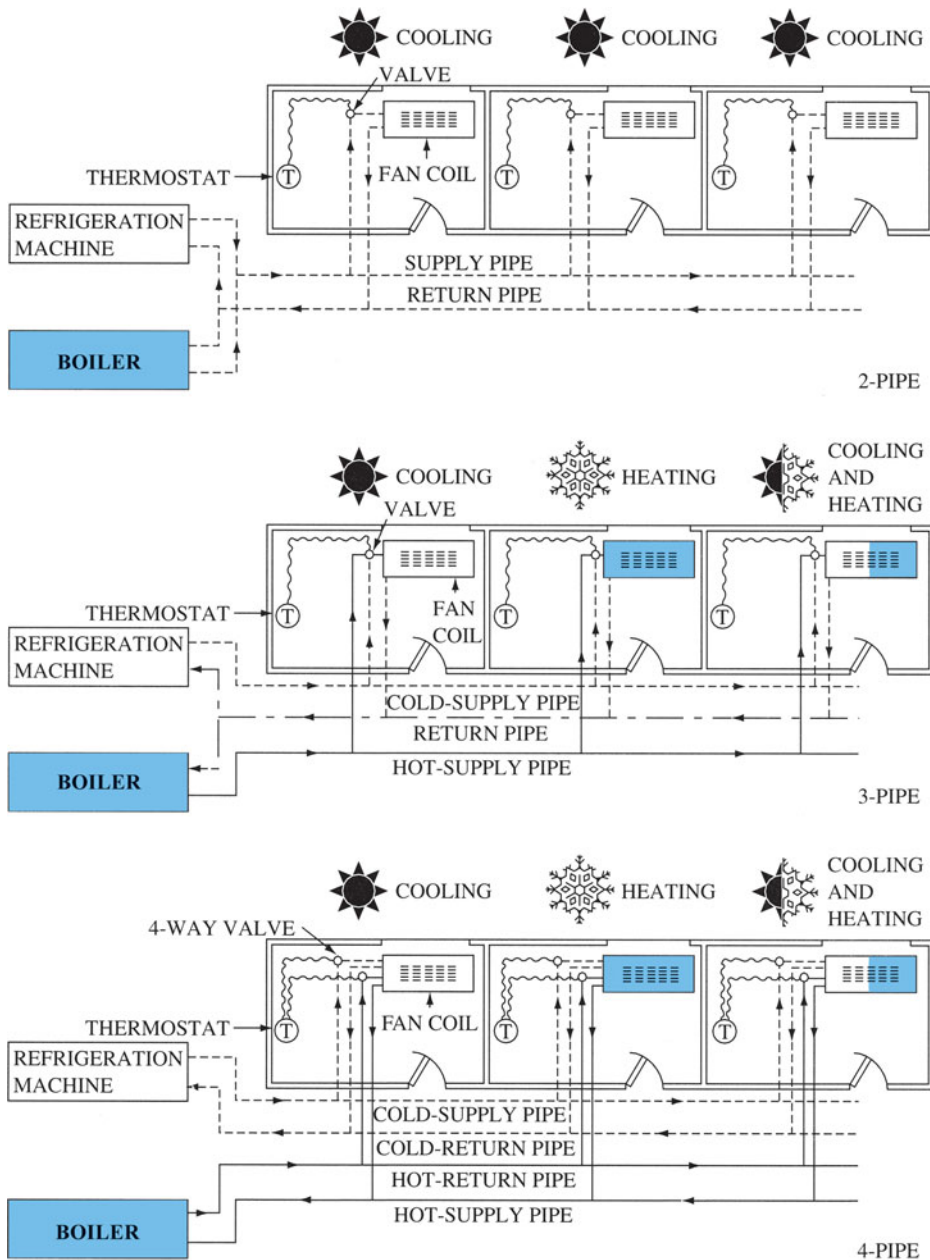

Figure 75-5 Typical fan coil unit, showing component parts.

Unit capacity is controlled by coil water flow, fan speed, or a combination of the two. A wall thermostat or the return-air temperature can be used to control the water flow. Airflow can be controlled by manual or automatic fan speed adjustment. Some units utilize variable-speed motors for modulated speed control. Outside air is introduced through a damper-controlled opening in the outside wall.

The size of the cabinet is designated in CFM of airflow and ranges from 200 to 1,200 CFM. These units may be installed on two-, three-, or four-pipe system designs, as illustrated in Figure 75-6.

With modifications to the cabinet, the same components are assembled in a horizontal ceiling-mounted version (Figure 75-7). Where hot water is not available for heating,

Figure 75-6 Three types of piping arrangements for fan coil units.

2-PIPE SYSTEM

EITHER HOT OR CHILLED WATER IS PIPED THROUGHOUT THE BUILDING TO A NUMBER OF FAN-COIL UNITS. ONE PIPE SUPPLIES WATER AND THE OTHER RETURNS IT. COOLING OPERATION IS ILLUSTRATED HERE.

3-PIPE SYSTEM

TWO SUPPLY PIPES, ONE CARRYING HOT AND THE OTHER CHILLED WATER, MAKE BOTH HEATING AND COOLING AVAILABLE AT ANY TIME NEEDED. ONE COMMON RETURN PIPE SERVES ALL FAN-COIL UNITS.

4-PIPE SYSTEM

TWO SEPARATE PIPING CIRCUITS – ONE FOR HOT AND ONE FOR CHILLED WATER. MODIFIED FAN COIL UNIT HAS A DOUBLE OR SPLIT COIL. PART OF THIS HEATS ONLY, PART COOLS ONLY.

Figure 75-7 Ceiling-mounted fan coil unit.

electric resistance heaters are installed in the cabinet after the cooling coil in the path of the air leaving the unit.

Another version of the room FCU is a vertical column design, which may be installed exposed or concealed in the wall. These are placed in common walls between two apartments, motel rooms, and so on. Water piping risers are also included in the same wall cavity. They are not designed for ducting but can serve two rooms through the addition of air supply grilles.

Small ducted FCUs with water coils may be installed in a dropped ceiling or in a closet, with ducts running to individual rooms in an apartment. These range in size from 800 to 2,000 CFM. The unit's cooling capacity is selected based on the desired airflow in CFM.

Larger FCUs, sometimes called unit ventilators, are used for school classroom conditioning. A single unit ventilator is installed below window level in each classroom with extension supply-air ducts and grilles running along the sill for the full length of the room. An opening in the back supplies outside air from a through-the-wall opening. The units include air filters to clean the air. Units are individually controlled, and this allows for differences in sun load,

depending on the orientation of the room. They also meet the ventilation requirements of local codes for classrooms.

75.4 PACKAGED UNITS

Packaged units that are used to condition offices, stores, and so on, where common air distribution is feasible, are self-contained air conditioners (Figure 75-8). They can be equipped with supply- and return-air grilles for in-space applications, or they may be remotely located with minor ducting arrangements. Sizes range from 800 to 15,000 CFM. For larger sizes, cabinet and fan-discharge arrangements permit flexible installations. These units approach the next category of equipment, called air handlers, but in general, they do not have the size and functions available in central station air handlers.

For all installations that include cooling, it is important to provide a drain for any water vapor condensing on the cooling coil. This water collects in a pan located just below the coil and should be piped away to an appropriate sanitary drain.

Induction Units

Induction units can be located for individual space cooling similar to FCUs. One significant difference is that induction units do not require fans. Centrally conditioned primary air is supplied to the unit at medium to high pressure. The primary air will pass through nozzles to create a low-pressure area that draws the air from the room through the induction unit and across the cooling or heating coils. Due to the high airflow required, this type of unit can be noisier than an FCU. Induction units are not designed to handle condensation, therefore the temperature and humidity of the primary air supplied from the central system must be properly controlled.

75.5 CENTRAL STATION AIR-HANDLING UNITS

Central station systems use one or more large AHUs equipped with fans, heating coils, cooling coils, and other accessories. They are centrally located in the building and

Figure 75-8 Packaged Unit.

Figure 75-9 Central multizone AHU, modular construction.

connected to ductwork that distributes the conditioned air to the desired areas (Figure 75-9).

Often these units are made in modules or sections that can be joined together on the job. This arrangement offers flexibility in the selection of components required for a specific installation.

The typical components found in a central station AHU with a single fan system are the filter, preheater, and cooling coil. These may all be enclosed in one cabinet, in a series of cabinets, or installed as separate components. For example, the preheating coil may be installed away from the cabinet in the ductwork near the entrance of the outside air into the building.

With a single fan, the suction pressure in the return system can create a negative pressure in many parts of the building. This can cause undesirable infiltration and put an extra resistance on the operation of the fan. The air

imbalance may also affect the operation of doors within the conditioned space, making them hard to open or causing them to slam shut. For these reasons, it is generally desirable to maintain a slightly positive building pressure. On a large system, the return-air fan is used to control the building pressurization. A schematic diagram of a two-fan central station air-handling system is shown in Figure 75-10. The return-air fan may be installed in the ductwork and not as part of the AHU.

TECH TIP

Central station air handlers can be very large. Some blower wheels are more than 20 ft in height and are powered by very large variable-speed motors. These blowers handle tens of thousands of cubic feet of air per minute. The blower area is actually a large room that may be located in a subbasement or on a separate floor in a high-rise building. When you enter this area you are actually walking into the blower chamber. Be careful when opening any door in this area or accessing the area because there may be a substantial pressure difference and the door can lunge open or closed.

75.6 AIR-HANDLER CABINET

Many air handlers are factory assembled as complete units, while others are factory assembled in sections and then put together at the job site. These units are enclosed in a cabinet typically made of galvanized steel that is coated on the outside with a polyurethane painted finish

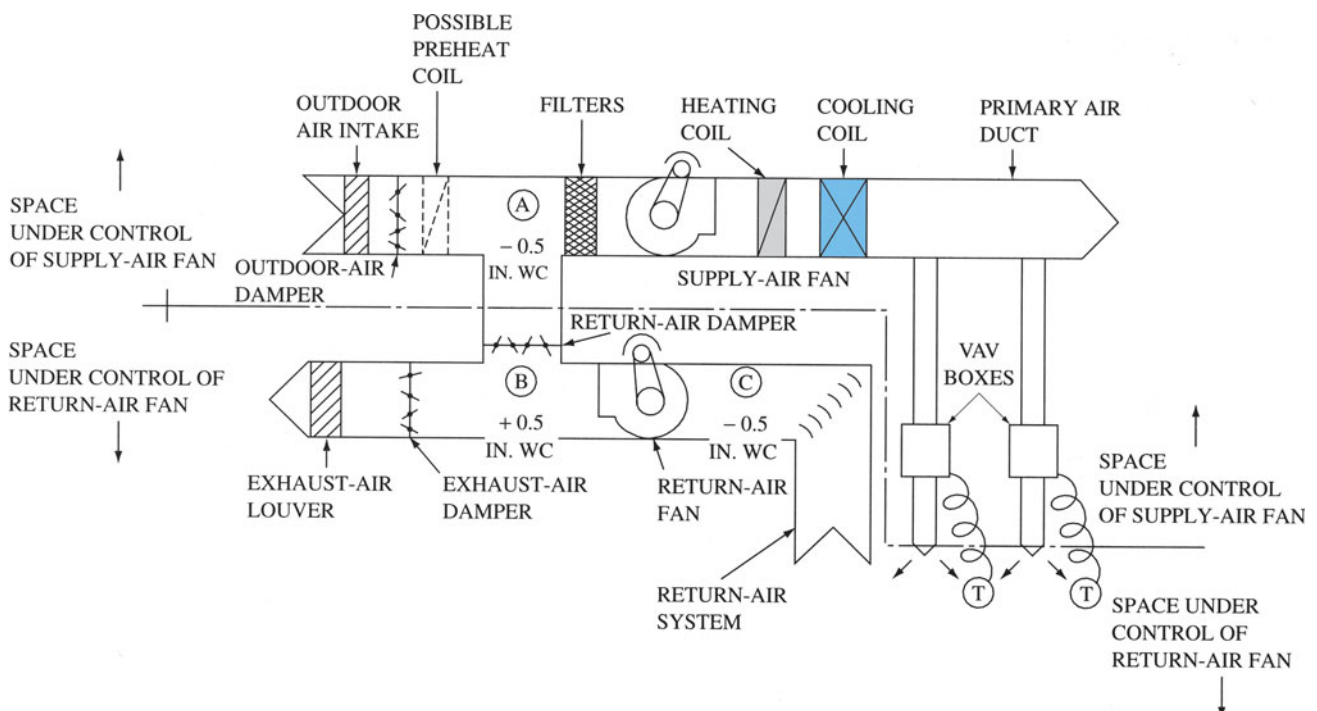

Figure 75-10 Schematic view of a two-fan central station AHU.

Figure 75-11 Air-handler door with painted outside coating.

(Figure 75-11). The inside can be coated with an antimicrobial finish. The cabinet is insulated to reduce sweating on the outside, which will occur during periods of high humidity. Some cabinets utilize double-wall construction with a layer of insulation sandwiched between an inner and outer wall. This provides for some rigidity that reduces the vibration of the cabinet. This also helps to provide a sound barrier, thereby reducing noise levels in the space created by the air handler. Access panels are provided to gain entry into the air handler.

TECH TIP

Although air-handler cabinets may be made of galvanized steel, there are still areas that may be subject to corrosion. The sheet-metal edge and any scratches deeper than the galvanized surface will expose the bare steel. This will eventually lead to rust, so be careful when installing or performing maintenance on a unit not to scratch the surface.

75.7 FAN CLASSES

The Air Movement and Control Association is an international standards organization that certifies fans, dampers, and other air-movement devices. The AMCA has classified fans into four classes based on fan performance. These classifications define upper and lower ranges of static pressure and outlet velocity for each class. Class 1 fans operate at the lowest pressures and velocities; Class 4 fans operate at the highest pressures and velocities. The AMCA standards require that the fan operate safely on or below the minimum rating for its class.

75.8 TYPES OF FAN DESIGN

There are two distinctly different types of fan design based on the direction of airflow through the fan: centrifugal and axial. Air flows into a centrifugal fan parallel to the motor shaft and is then spun outward, through the fan blades, by the centrifugal motion of the fan. The fan housing then channels the airflow toward the fan outlet. The air movement

Figure 75-12 Many units use propeller fans for condenser fans.

in an axial fan is parallel to the shaft. A propeller fan is an example of an axial fan. Propeller fans are often used in residential condensing units (Figure 75-12).

TECH TIP

Centrifugal fans are designed to produce high static pressures, while axial fans provide high volumes of air. Centrifugal fans work very well on duct air-distribution systems, while in contrast axial fans are not capable of producing enough static pressure to move air through long ducts. However, axial fans are very effective in moving air through the large openings typically required for building ventilation. Each fan type has its purpose and application, and they are not interchangeable.

75.9 CENTRIFUGAL FANS

Centrifugal fans are the workhorse of the air-conditioning industry. These fans are sometimes called “squirrel cage” fans due to the shape of the impeller wheel. They are the fan of choice when “pumping” air in high volumes, against high static pressure. A ductless system may use a centrifugal fan to deliver air directly to a room or use a blower in a split system to pump air through an elaborate duct system to condition an entire residence. These fans are also used in many ventilation applications.

There are several different blade designs used with centrifugal fans. The two main types of centrifugal fans used in air-conditioning work are the forward-curved blade, which is most common, and the backward-curved blade.

Figure 75-13 Centrifugal fan with a scroll housing.

The advantage of the backward-curved blade is that it is nonoverloading. The disadvantage is that it is noisier.

Centrifugal Fan Housings

Centrifugal fans can be divided into three housing types: scroll, tubular, and plug, the last of which has no housing. The scroll housing is the most widely used for air conditioning and heating. This housing design directs the airflow from the fan blades down a channel at a 90-degree angle from the drive shaft. Figure 75-13 shows a centrifugal fan with a scroll housing.

Tubular centrifugal fans have a housing that looks like a tube or pipe. The air is drawn in parallel to the drive shaft and spun out of the blades. It is then redirected out the other end of the “tube,” giving it parallel airflow to the drive shaft when exiting the fan housing. This centrifugal fan is used to ventilate heat, fumes, or smoke in commercial or industrial applications.

The third and least used centrifugal fan is called a plug fan. It is a design that has no housing. These fans are installed directly into plenums of AHUs to pressurize the complete unit. This fan design is less efficient but offers flexibility in unit design and can reduce unit size.

SERVICE TIP

The amp draw of a centrifugal blower will actually decrease if the air to the blower is blocked. A centrifugal fan will turn faster if it is not actually moving air, and the motor amp draw decreases because of the reduced load on the blower.

75.10 BLADE DESIGN

There are six types of centrifugal fans based on the design and shape of the blades used to move the air: forward curved, backward curved, airfoil, radial, radial tip, and backward inclined.

Forward-Curved Centrifugal Fans

Forward-curved centrifugal fans are the most popular blade design for residential systems. This blade design curves the blade’s leading edge toward the direction of airflow. This adds resistance to the forward motion of the fan wheel, reducing fan speed, noise, and efficiency. This blade design can cause motor overloading if the static pressure is decreased past design limits of the fan. One advantage to this design is that bearing size is reduced and bearing life extended because of the fan’s lower rpm.

SERVICE TIP

The indoor blower in most furnaces and heat pumps is a forward-curved centrifugal fan. These blowers are not designed to operate in free air; they need to have some resistance to airflow. Technicians often try and use blowers removed from old equipment as fans to cool the work area. Some restriction must be added to the opening of either the fan inlet or outlet to keep the fan operating without overloading the motor.

Backward-Curved Centrifugal Fans

Backward-curved fan blades have a leading edge that trails the airflow, producing little resistance to the fan wheel’s forward motion. The speed of one of these blowers is nearly twice the speed of a forward-curved blower. This low-resistance design increases both efficiency and noise due to its higher rpm. These fans are larger in design and require larger drive shafts and bearings than do forward-curved blowers. Figure 75-14 shows a centrifugal fan with backward-curved blades. A comparison of forward- and backward-curved blades is shown in Figure 75-15.

Airfoil Centrifugal Fans

Airfoil blade blowers are a variant of the backward-blade design. This is the most efficient centrifugal blade design

Figure 75-14 Backward-curved centrifugal fan.

Figure 75-15 Schematic view of the construction of (a) backward-curved fan and (b) forward-curved fan.

due to its very low resistance to airflow. However, this resulting higher efficiency covers only a small area of its performance curve in relation to other backward-curved fan blades; and has a higher cost associated with it. This often reduces its use to only high-static-pressure applications where additional cost can be justified. In most other ways, the airfoil blade design reflects the backward-blade design's operational advantages.

75.11 AXIAL (IN-LINE) FAN

Axial fans are divided into three types based on housing design: the propeller fan, the tube axial, and the vane axial. The propeller type will handle large volumes of air for low-pressure applications. It has high usage for exhaust fans and condenser fans. Vane-type fans are highly efficient but noisy. The blade pitch can be adjusted to control the amount of air the fan handles.

SERVICE TIP

The amp draw of a propeller fan will increase if the air leaving the blower is blocked. Propeller fans do not work well against the high-pressure difference created when the fan outlet is blocked. They slow down, putting more load on the fan motor and increasing its amp draw.

Propeller Fans

The propeller fan shown Figure 75-16 is the most familiar axial fan design. It consists of a fan shaft with two or more blades attached at a 90-degree angle to the shaft. Some of these fans will have a hub assembly that attaches the blades to the shaft. This hub assembly allows for maintenance and modification. Air is pulled through the fan blades parallel to the shaft and is blown outward. These fans are high speed and as a result produce high noise levels. Axial fans operate well in low-static environments and can move high volumes of air.

The propeller fan is generally used as a condenser fan on air-conditioning systems. These fans are generally shrouded to improve performance but do not use a true housing. Propeller fans typically have two to six blades. This

Figure 75-16 Propeller fan.

fan works well in a low static pressure and relies on blade pitch to determine efficiency.

SERVICE TIP

The propeller fans used with most air-conditioning applications have a cup shape. The cup pushes the air forward. The rotational direction of a propeller fan can be determined by observing the direction of the blade cup. When looking at the blade so that the cups are visible, the edge of the blade cup that is farthest away from the observer is the leading edge. The blade should turn toward the leading edge. Figure 75-17 illustrates the rotational direction and airflow direction of a typical propeller fan.

Tube Axial Fan

The tube axial fan has a housing that resembles a pipe or tube. The blades are in close tolerance to the housing. Flat blade or foil design blades are most common. These fans are widely used in ventilation, such as warehouses or in structures where fume venting is required.

Vane Axial Fan

The vane axial fan is the most efficient axial design and can operate at higher static pressures than other axial designs. The efficiency of this housing comes from vanes added in the path of the airflow to reduce "swirling" of the air. These fans move high volumes of air and produce high noise levels.

Figure 75-17 A propeller fan turns toward the leading edge of the fan; the leading edge is farthest from the viewer.

and may require noise dampers in some applications. This type of design can offer an adjustable blade pitch that can be used to vary the amount of air moved by the fan. These fans are often applied to variable-air-volume systems because of their ability to easily vary the airflow.

75.12 TYPES OF FAN DRIVES

The fan drive type refers to how the motor motion is transferred to the blower. There are two types of drive arrangements for air-conditioning fans: direct drives (Figure 75-18) and belt drives (Figure 75-19). With direct drive, the fan driveshaft or fan wheel is attached to the motor's drive-shaft. This method is normally applied to lower-torque applications and lower-horsepower motors. This is the most efficient design because there is no loss due to slip. Belt-driven motors use belts, such as v-belts, to attach the motor driveshaft to the fan driveshaft. Normally, large-torque applications use belt drives. Torque is improved because the motor turns over several revolutions for each revolution of the blower. Other design requirements, such as size or

Figure 75-18 On the left is a direct drive centrifugal fan; on the right is a direct drive propeller fan.

(a)

(b)

(c)

Figure 75-19 (a) Belt drive blower; (b) fan, belt, and motor arrangement for large air-handling unit; (c) belt-driven blower for a stand-alone computer room HVAC unit.

maintenance requirements, may favor a belt-drive design. The fan speed can be changed on a belt-drive blower by changing the pulley size or in some cases by adjusting the pulley sheaves without changing the entire pulley out.

SERVICE TIP

The motors used in most fans and blowers are called air-over motors. They depend on airflow over the motor to cool the motor. These motors have openings in the end bells of the motor for airflow. If these openings are plugged with lint, dust, pet hair, or other particulate matter, the motor will overheat. Dirty air filters or dirty evaporator coils can severely reduce system airflow and can also cause the blower motors to overheat from lack of cooling. Most of these motors have internal thermal overloads that will shut down the motor until it cools off. This can take over an hour. (Note: Some totally enclosed motors are also listed as air-over motors and may be designated as totally enclosed air-over or TEAO motors.)

Belt-Drive Blowers

For belt-driven blowers, the speed of the fan is determined by the ratio of the motor pulley to the fan pulley. Increasing the size of the motor pulley will increase the rpm of the blower. Increasing the size of the blower pulley will decrease the rpm of the blower. For example, to calculate the fan rpm with a motor rpm of 1,750, a 3-in-diameter motor pulley, and a 6-in-diameter fan pulley, use the following formula:

$$\text{Fan rpm} = \frac{\text{Diameter of motor pulley} \times \text{motor rpm}}{\text{diameter of fan pulley}}$$

$$\begin{aligned}\text{Fan rpm} &= \frac{3}{6} \times 1750 \\ &= 875 \text{ rpm}\end{aligned}$$

SERVICE TIP

A relatively small change in pulley size can make a big difference in motor load. When adjusting the pulleys or belt on a belt-drive blower, it is important to check the amp draw once the motor pulley and belt have been adjusted to make certain that the motor is not drawing excessive current, which would result in its overheating and failing.

SAFETY TIP

Belts and pulleys are major pinch points and should be regarded with caution when changing belts or making adjustments. The power source to the equipment should be locked out when changing or adjusting drive components. Any belt or fan guards that are removed to work on the equipment should be replaced before putting the equipment back into service.

Direct-Drive Blowers

Direct-drive motors are available with multiple speed windings. The speed can be changed by switching wires in the motor terminal box. This can be done by the control system so that a different speed can be used for heating and cooling, or it can be a manual setting used to match the blower to the resistance of the duct system. Direct-drive fan motors are usually the PSC (permanent split capacitor) type. Higher-efficiency systems typically use ECM brushless dc motors. These motors can be programmed for a wide range of operating conditions. They can vary the airflow based on the equipment operating cycle or based on the resistance to airflow.

Variable-frequency drives are also becoming popular to control the speed. This type of system uses an inverter to modify the drive power output into many steps rather than into a smooth sine wave. Instead of a fixed voltage and frequency, the motor input is variable, which allows for changeable motor speed without losing torque. However, this requires motors rated for inverter duty, as standard motors will overheat. Although the variable-frequency drive motor efficiency is lower than a standard motor drive, the overall power required should be less. This is because the motor power requirement can be more evenly matched to the load. Systems can be designed to allow for the control of fan speed down to as low as 10 percent of the normal design speed.

SERVICE TIP

When adjusting the speed of a blower, check the motor amperage with the blower door closed. With the blower door open, more free air is allowed to enter the blower and the amp draw will be higher than it would be with the door closed.

75.13 FAN LAWS

A fan's performance varies depending upon the conditions it operates under. There is no such thing as a 400 CFM fan. A fan that moves 400 CFM of air at one condition might only move 200 CFM at another condition. The amount of air a fan moves, the speed of the fan, the amount of pressure difference produced across the fan, and the motor horsepower required are all interrelated.

Fan speed is directly related to the amount of air a fan can move: doubling the fan speed doubles the airflow. Take, for example, a fan moving 400 CFM against a static pressure of 0.1 in wc turning 500 rpm and using a ¼-hp motor. Doubling the speed from 500 rpm to 1,000 rpm will double the CFM from 400 CFM to 800 CFM. The static pressure difference across the fan increases more rapidly. Doubling the fan speed increases the static pressure by a factor of 4. Doubling the speed of the same fan from 500 rpm to 1,000 rpm will increase the static pressure across the fan from 0.1 in wc to 0.4 in wc. The horsepower requirement to accomplish this increases even more dramatically. Doubling the fan rpm will require 8 times the horsepower! So increasing the fan speed from 500 rpm to 1,000 rpm will increase the horsepower requirement from ¼ hp to 2 hp.

The relationship between changes in speed (rpm), air volume (CFM), static pressure (SP), and power in brake horsepower (Bhp) are described by a set of formulas called fan laws. The fan laws in classic form are:

$$\frac{\text{CFM}_2}{\text{CFM}_1} = \frac{\text{rpm}_2}{\text{rpm}_1}$$

$$\frac{\text{SP}_2}{\text{SP}_1} = \left(\frac{\text{rpm}_2}{\text{rpm}_1} \right)^2$$

$$\frac{\text{Bhp}_2}{\text{Bhp}_1} = \left(\frac{\text{rpm}_2}{\text{rpm}_1} \right)^3$$

These can be algebraically rearranged to find the new airflow, speed, static pressure, or horsepower.

$$\text{New CFM} = \text{Old CFM} \times \frac{\text{New RPM}}{\text{Old RPM}}$$

$$\text{New RPM} = \text{Old RPM} \times \frac{\text{New CFM}}{\text{Old CFM}}$$

$$\text{New SP} = \text{Old SP} \times \left[\frac{\text{New RPM}}{\text{Old RPM}} \right]^2$$

$$\text{New BHP} = \text{Old BHP} \times \left[\frac{\text{New RPM}}{\text{Old RPM}} \right]^3$$

EXAMPLE 75-1: RESULT FROM INCREASING FAN CFM

What would be the resulting operating condition if the airflow moved by a fan operating at 300 rpm, 0.15 in wc static, and 0.2 Bhp was increased from 600 CFM to 800 CFM?

First find the new speed.

$$\text{New rpm} = 300 \text{ rpm} \times (800 \text{ CFM} / 600 \text{ CFM}) = 400 \text{ rpm}$$

Next, use the new rpm to find the new static pressure.

$$\begin{aligned} \text{New SP} &= 0.15 \text{ in wc} \times (400 \text{ rpm} / 300 \text{ rpm})^2 \\ &= 0.15 \text{ in wc} \times 1.78 = 0.27 \text{ in wc static} \end{aligned}$$

Finally, use the new rpm to find the new horsepower.

$$\begin{aligned} \text{New Bhp} &= 0.2 \text{ Bhp} \times (400 \text{ rpm} / 300 \text{ rpm})^3 = \\ &= 0.2 \text{ Bhp} \times 2.37 = 0.47 \text{ bhp.} \end{aligned}$$

The new operating conditions are at 400 rpm, 0.27 in wc static, and 0.47 Bhp to increase the airflow from 600 CFM to 800 CFM.

Fan Performance Tables

Manufacturers publish performance tables for each specific fan. Performance tables show the fan performance at specific operating conditions. Performance tables show the fan CFM compared to the static pressure. Other information included in fan performance tables are the outlet velocity, fan rpm, and motor horsepower requirement for the selected condition.

Figure 75-20 Typical fan curve with CFM along the bottom and all other data on the side.

SERVICE TIP

Very often the fans, motors, and drives are all located in the airstream. If this is the case, the heat from the motor, the frictional heat from the belt drives, and the heat from the bearings need to be added to the total cooling load capacity.

Fan Performance Curves

The fan curve is a graphical representation of fan performance. Airflow is typically plotted along the x-axis, and power, pressure, and efficiency are plotted along the y-axis (Figure 75-20). Fan curves are used in system design to select a fan that is capable of moving the correct amount of air at the desired system operating condition. There will be a best match for air flow, efficiency, and power for any given fan. Fan curves can also be used to predict the effect any change in operating conditions will have on fan performance. A fan or a family of fans may be compared on one chart.

75.14 MECHANICAL AIR FILTERS

Mechanical air filters can be of the throwaway or the cleanable type. The simplest and cheapest construction is the dry disposable type. The frame is generally made of cardboard and the filtering medium is often bonded glass fiber, wool, felt, or synthetics. Extended surface filters are pleated to create a larger filter surface. If they are cleanable, they are more rugged than the disposable type with sturdier metal frames. Cleaning can be accomplished using steam, water, or detergents.

Viscous impingement-type filters will be coated with a sticky substance such as oil and come in both the throwaway and cleanable types. The sticky surface will help to catch the contaminant particles as they pass through the screen. Because of this, the filter does not need to be as dense and can be made with a higher porosity. The advantage to higher porosity is that there is less restriction to airflow. However, impingement-type filters will not work well if the adhesive surface is full of dirt. The air velocity across the filter is also important. If the air travels too quickly,

Figure 75-21 Roller-type air filter.

some contaminants will slip through the filter. If the velocity is too low, the contaminants will not be forced into the adhesive and may simply pass through. If a viscous impingement filter is cleaned, the adhesive needs to be reapplied. A roller-type cleanable air filter used for a large industrial air filtration system is shown in Figure 75-21. The filter media is periodically rolled as it becomes loaded with dirt.

SERVICE TIP

MERV stands for Minimum Efficiency Reporting Value. Higher MERV ratings are provided for more efficient air filters.

High-efficiency particulate air (HEPA) filters have very high filtration efficiencies. Typical cartridge filters range from 65 to 95 percent, while HEPA filters can be as high as 99.9 percent. This type of filter is often located in the air supply for surgical suites, intensive care units, and electronic or microprocessing clean rooms. Due to its high efficiency and dense structure made of submicron glass asbestos fiber, the filter will plug up quickly if no provision is made for a prefilter system.

Antimicrobial Treatment

Some air handlers now utilize antimicrobial-coated steel on the inner sections of the unit. Silver ions are blended into the paint that is used for the inner surfaces. The silver is slowly

released to react with any bacteria or other microbes that try to accumulate and grow. This same application is also used to treat filter media. This type of application is particularly well suited for hospitals, schools, and restaurants.

75.15 ELECTRONIC AIR FILTERS

Like applications for the HEPA filter where high filtering efficiency is required, electronic air filters are often used. An advantage to electronic air filters is that they can be cleaned, while most HEPA filters are replaced once they become dirty. One type of electronic air filter applies a charge to the dust particles by passing them through an ionizing zone of vertical wires that have a positive charge. The dust passing through the filter will be positively charged and attracted to negatively charged plates also located in the airstream. The plates are cleaned by turning off the power and washing the plates with a nontoxic detergent solution. Prefilters or screens are commonly used with this type of filtering system.

CAUTION

Electronic air filters can have charges as high as 10,000 to 12,000 V. All electrical power must be disconnected from this type of filter prior to service.

Another type of electronic filter uses a charged filter medium of glass fiber held in place by nonconductive frames. A charge of 10,000 to 12,000 V (DC) is common. Unlike the electronic air cleaners that use metal plates, this type of cleaner also acts as an impingement filter due to the construction and arrangement of the glass fiber filter media.

75.16 ULTRAVIOLET GERMICIDAL LAMPS

Odor and fungus may develop in the wet sections of an air handler. Ultraviolet lamps can be located directly after the cooling coil section and directed toward the coil and the drain pan (Figure 75-22). The lamps should be powered by a separate power source so as not to cycle off and on with the fans. Ultraviolet lamps should not be used with polyester or cotton-type filter elements, as the ultraviolet light will break down the filter media over time. Fiberglass filter media is recommended. The normal color for the lamps is blue, and as the color begins to change to red, the bulbs should be replaced.

CAUTION

Ultraviolet light can be harmful to your eyes and skin. Never open up an air handler that has ultraviolet lamps until the lamps have been turned off.

Figure 75-22 Ultraviolet germicidal lamp.

SERVICE TIP

The surface of an ultraviolet lamp is very sensitive and just the oil from your fingerprints can lead to premature failure of the lamp. Always use gloves when handling the lamp and wipe away any film to clean the lamp after handling.

SERVICE TIP

Central AHUs are generally arranged so that it is not possible to operate both the heating and cooling coils at the same time. This is because the energy-conservation codes do not permit it and there would be no advantage since a single-zone unit can provide only heating or cooling at one time.

75.17 WATER HEATING COILS

The heating coil is often selected for hot water heating because most furnaces today are either forced hot air or hydronic systems rather than steam. A hot-water system is also simpler in its design. Water coils are available in depths of one, two, three, four, five, six, and eight rows deep with various types of circuiting. They are free draining and are provided with $\frac{1}{4}$ -in NPT fittings in the header for draining and venting. Tubes are staggered to improve thermal efficiency.

The water heating coil is most always a counterflow design for the best thermal efficiency. The incoming water will be piped to enter at the air outlet side of the coil (Figure 75-23). In this way there is more even heat transfer across the entire coil from the air inlet to the outlet. The water flow through the coil is generally regulated by a valve on the outlet side. A three-way mixing valve is shown in Figure 75-24. Some air handlers utilize heat-recovery coils, which circulate water or glycol that has absorbed waste heat (Figure 75-25).

Figure 75-23 Counterflow water coil.

Figure 75-24 Flow through a water heating coil.

Figure 75-25 Piping for a hot-water heat-recovery coil.

Figure 75-26 Steam traps are located in the condensate return line from the steam heating coil.

75.18 STEAM HEATING COILS

If the building has a ready supply of steam available, then steam heating coils may be used rather than water. Low-pressure steam applications are rated at 15 psig or less. Medium-pressure steam applications are rated at greater than 15 psig but generally no greater than 35 psig. Steam flow through the coil is typically controlled by a valve at the inlet rather than at the outlet. In addition, a steam strainer is required at the inlet, and a steam trap must be located at the outlet. A typical piping arrangement for a low-pressure steam heating condensate return line is shown in Figure 75-26.

More heat will be transferred in a steam coil as compared to a water coil where only sensible heat is transferred. A steam coil transfers both sensible and latent heat. Due to this additional heat transfer, a steam coil will be smaller in overall size as compared to a water coil. This allows for a much larger water coil to be replaced by a smaller steam coil if space limitations are a concern.

It is important for all of the steam to condense in the coil, and that is the function of the steam trap. If the trap is hung open and steam is allowed to leave the coil, the efficiency will decrease because latent heat is not being transferred. If the trap is frozen shut, the steam flow will back up and the air passing across the coil will no longer be heated. Opening the bypass valve around the trap will bring the air temperature back up, but this should only be a temporary correction and the trap should be isolated and then repaired or replaced.

CAUTION

Most steam valves for heating systems are designed to operate with maximum steam pressures of up to 35 psig and no more. Be sure to check the rating of any steam valve that you install to make sure it is correct for that system.

Figure 75-27 Water drain located at low point of air duct.

75.19 WATER-COOLING COIL

The chilled-water cooling coil is similar in construction to the hot-water heating coil. The cooling coil, however, will probably be deeper (more rows deep), since more surface is necessary for dehumidification. Also, due to the air dehumidification, it is necessary to allow for condensate to be drained away from the unit. This will require a condensate pan and drain and possibly a condensate pump depending on the location of the air handler. Some systems have drain lines located in the air duct to remove any additional water that may condense in the ductwork (Figure 75-27).

Water-cooling coils should also be piped as counter-flow heat exchangers. The chilled water entering should be supplied to the coil at the air outlet side of the coil. In this way the chilled water will first absorb heat from the coldest air leaving the coil. A typical chilled-water piping system for a large air handler is shown in Figure 75-28.

Figure 75-28 Typical chilled-water piping system for a large air handler.

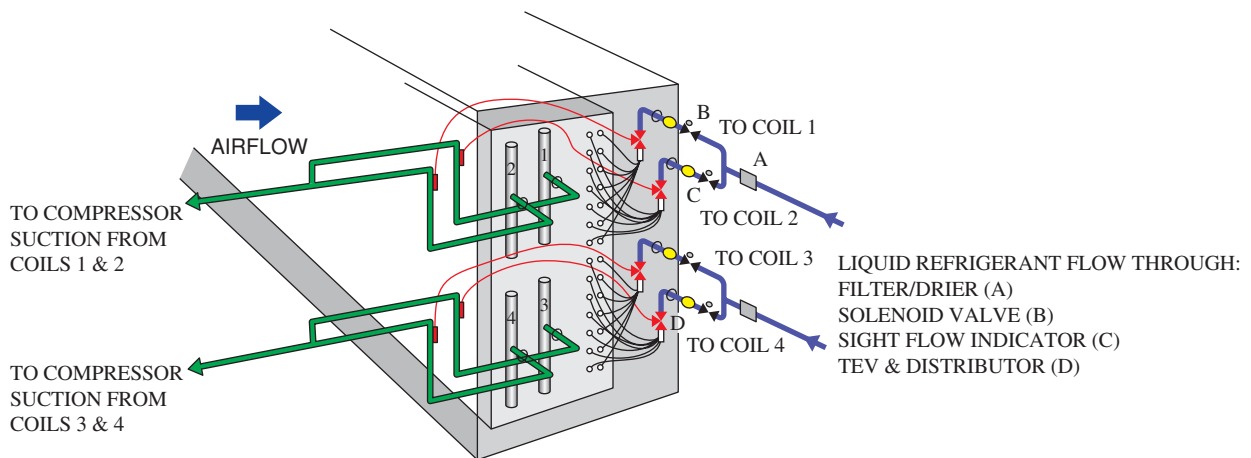

Figure 75-29 Direct expansion four-row face-split cooling coil.

75.20 DIRECT EXPANSION COOLING COILS

Direct expansion cooling coils can be configured for multiple stages of capacity control. Multiple expansion valves along with unloader solenoid valves, hot-gas bypass valves, and liquid-line solenoid valves are used. The direct expansion coil shown in Figure 75-29 is referred to as a four-row face-split coil. This coil uses four expansion valves with two supply lines. The refrigerant flow can be sequenced through the different coils—one, two, three, or four—depending on the load demand. The flow operating sequence is generally that the first coil to come on is the last one to come off.

SERVICE TIP

Many direct expansion coils come sealed with pressurized dry air inside the coil. If the protective caps are removed from the coil, air and moisture will be allowed to enter. If the coil is being installed and the connections are not complete, the coil should be charged with nitrogen and recapped until the final installation can be completed.

The suction connections on a direct expansion cooling coil are typically on the air inlet side of the coil. Expansion valves should be mounted as close to the coil as possible. The location of the expansion valve thermal bulb is very important. These are commonly mounted on the vertical line located after the refrigerant outlet header. In addition to the expansion valve for the control of refrigerant flow, distributors are often used to channel the refrigerant evenly to all sections of the coil (Figure 75-30).

75.21 HUMIDIFIERS

Comfort is greatly affected by the relative humidity of the air. At a temperature of 72°F and a high relative humidity level of 75 percent, you would feel very uncomfortable. At

Figure 75-30 Refrigerant distributor.

the same temperature of 72°F with a lower relative humidity of 35 percent, you would feel cozy. At 72°F and a 10 percent relative humidity, you would probably feel cool. Too much or too little humidity is unpleasant, so it is important to maintain the proper humidity.

Cooling coils often are used for dehumidification purposes, particularly for moist air. The air temperature falls below the dew point as it passes across the coil and the water is removed. The opposite is true during the heating season. Very often in the heating months, the air may be too dry. Hygroscopic materials such as wood, leather, paper, and cloth require a fixed amount of moisture to preserve their proper condition. These materials shrink when they dry out. If moisture loss is rapid, warping and cracking can take place. To retain their quality, proper humidity must be maintained. A low humidity can cause shrinkage of the framing around doors and windows. This increases the infiltration of outside air into the building, which leads to greater energy usage.

From a health standpoint, medical science reveals that the nasal mucus contains some 96 percent water. Doctors indicate that the drying out of the nasal tissues in winter

Figure 75-31a (a) Steam humidifier; (b) steam humidifier vertical manifold.

helps to initiate the common cold. Maintaining proper humidity can greatly affect one’s susceptibility to colds. Also, proper humidity levels permit lower comfort temperatures, allowing thermostats to be set lower, which results in energy conservation.

TECH TIP

One of the limiting factors in maintaining proper humidity is the condensation that occurs on windows in winter. Table 75-1 shows the outside temperature at which condensation will occur for various types of glass.

Humidifiers are used to add moisture to the air. The steam-grid type is highly recommended because it offers simplicity in construction and operation, and humidification can be closely controlled (Figure 75-31a). The live steam is directly admitted through a control valve into the airstream (Figure 75-31b). The steam will heat the air and add water vapor to it. Another style of humidifier, referred to as the steam-pan type, is used when the introduction of steam directly into the airstream is undesirable. The vaporization of water from a pan provides moisture to the conditioned air. In applications where steam is unavailable, hot water sprayed directly into the airstream can be used. Water spay will provide optimum performance in applications where the humidity level is fairly low and precise control is not required.

Table 75-1 Outside Air Temperature Effect on Window Condensation

Window Type (@ 70 °F Inside Temperature)			Inside Relative Humidity Resulting In Condensation
Single Pane	Double Pane	Triple Pane	
43 °F	18 °F	10 °F	50%
38 °F	11 °F	0 °F	45%
34 °F	2 °F	–10 °F	40%
28 °F	–8 °F	–25 °F	35%
22 °F	–20 °F	–35 °F	30%
15 °F	–30 °F		25%
8 °F			20%
0 °F			15%
–11 °F			10%

TECH TIP

Humidifiers that are not properly maintained are subject to mold and mildew growth. Because of concerns with indoor air quality, it is very important that any humidifier be properly maintained to prevent and remove mold and mildew formation. When mold and mildew dry out, spores are released that become primary irritants in a building. Before a system is restarted, you must remove all mold and mildew. Follow the equipment manufacturer's procedures and all local health code requirements when removing mold and mildew from humidifiers or any other part of a building.

air moved in CFM compared to the power required in Bhp (brake horsepower) and the resistance in inches of water column. The performance of any particular fan can be accurately predicted using fan performance curves.

Filters in the airstream can be disposable or cleanable depending on their design. HEPA and electronic filters are used where high-efficiency filtration is required. Humidification of the airstream allows for increased human comfort and reduces the drying out and shrinking of windowsills and doors. Microbial treatments and ultraviolet lamps are used to reduce the buildup of mold and mildew. Depending on the application, an air handler may include any arrangement of these accessories to provide for the proper distribution and treatment of air supplied to a building.

UNIT 75—SUMMARY

Air-handling units come in many sizes and configurations depending on the application. For individual space heating and cooling, fan coil units may be used supplied with hot or cold water from a central plant. Packaged air handlers can be factory assembled or put together as sections on the job site. Cooling coils can be of the indirect expansion type using chilled water or the direct expansion type with multiple expansion valves for capacity control.

There are two distinctly different types of fans: centrifugal and axial, based on the direction of airflow through the impeller. The centrifugal fan is used the most for moving air through duct systems. Propeller fans are used for moving air at relatively low-pressure differences, as in condenser fans. The fan laws are a group of formulas that describe the relationship between the variables affecting airflow, including fan speed, air volume, CFM, static pressure, and horsepower. The fan curve is a graphical representation of fan performance. Fan curves generally show the volume of

WORK ORDERS

Service Ticket 7501

Customer Complaint: AHU Supply Fan Motor Is Tripping

Equipment Type: 75-Ton AHU with Centrifugal Fan

The technician arrives at the site and speaks to the maintenance department supervisor. They recently replaced belts on the air-handler supply fan and replaced a worn adjustable pulley sheave and now the AHU will not stay online. First the technician starts the unit and measures the amperage drawn by the supply fan motor and finds it to be too high. Next the technician visually checks the supply fan belts and finds that one of the new belts is already wearing on one side.

It is now obvious that the sheave-shaft alignment and overhang are not correct (Figure 75-32). The belt tension was also too tight (Figure 75-33). When maintenance replaced the motor sheave, they did not align it

Figure 75-32 (a) Sheave-shaft alignment; (b) sheave-shaft overhang.

Figure 75-33 Supply fan belt deflection.

properly, causing the motor to overload. The technician removes the belts and adjusts the sheave alignment correctly. The technician reinstalls the belts, aligns the belts, and restarts the AHU. The unit is now operating within design specifications.

Service Ticket 7502

Customer Complaint: Humidifier Will Not Work

Equipment Type: Electric-Powered Steam-Pan Humidifier

The technician answers a complaint about very dry air in a dental office. The office has a small central station air handler located in a utility room in the back of the building. Opening the access panels to the unit, the technician finds an electric-powered steam-pan humidifier. Measuring a zero voltage drop across the electric heater element indicates that it needs replacement.

The technician removes the old element and cleans the pan of scale and mildew. The scale and mildew are the result of normal use, and the minerals normally found in the makeup water tend to collect in the pan. The technician replaces the element with the exact factory replacement part and restarts the humidifier. The humidifier is now operating normally. The technician recommends regular maintenance and a water softener installed on the makeup water to the pan.

Service Ticket 7503

Customer Complaint: No Heat

Equipment Type: Weather-Tight Central Station Air Handler

The technician answers an emergency no-heat call at a large dry-cleaning establishment. The central station air handler is a large weather-tight unit located on the building's roof. The technician pulls hard to get the door to open as it is under a slight negative pressure inside the air handler. There are multiple fan and coil arrangements located inside supplying air individually to multiple zones. Each fan arrangement has its control mounted beside it. One of these is flashing an alarm signal. The alarm code manual is hanging by a small piece of chain next to the control panel, and the technician looks up the fault code to find that it is for a low air-supply temperature.

The heating coil is easy to distinguish from the cooling coil because of the steam supply and return piping

attached to it. The steam control valve is in the fully stroked wide-open position as it should be calling for heat. The technician uses a heat gun to check the surface temperature of the steam coil and finds that it is no hotter than the airstream passing over it. The smaller steam preheat coil at the entrance to the air stream registers a temperature of over 200°F and is the only source of heat. The technician locates the steam trap at the outlet of the heating coil and opens the bypass valve around it slowly to minimize any water hammer. Almost immediately the heating temperature begins to increase. Next the technician closes the valves on either side of the steam trap and slowly breaks the connection to make sure that there is no steam pressure remaining. The steam trap is replaced and put back into service, and now the supply air temperature is normal.

UNIT 75—REVIEW QUESTIONS

- Although air-handler cabinets may be made of galvanized steel, there are still areas that may be subject to corrosion. Why?
- Describe the two general types of AHUs.
- List the components of an FCU.
- Often around fluorescent lights in a dropped ceiling there is a narrow slit. What is the purpose and advantages of this application?
- Where are larger FCUs most commonly used?
- In FCUs that have cooling coils, how is the dehumidification condensate disposed of?
- Explain the advantages that unit-ventilator-type FCUs have in schools.
- List the major components in most AHUs.
- State the reason a properly sized AHU fan and motor usually requires field adjustment during the final start-up/commissioning phase.
- Name the two basic types of fans used in most AHUs.
- On an AHU with a centrifugal fan, what are two advantages of backward-curved airfoil blades?
- State where axial fans are commonly used.
- Tell why actual motor voltage and amperage should be field measured and logged under full load conditions.
- In a heating coil, what advantage does heating water have over steam?
- When referring to humidity, why is a cooling coil deeper (more rows) than a heating coil?
- How should ultraviolet germicidal lamps be handled?
- Describe the problems associated with poorly maintained humidifiers.
- If the inside temperature is 70°F and the RH is 50 percent, how low would the outside temperature have to be to form condensation on a double-pane window? Refer to Table 75-1.
- Why is the steam-grid humidifier recommended?
- What horsepower motor will be required to increase the airflow of a fan to 1,000 CFM if a ¼-hp motor is required to move 800 CFM?

21. What are the characteristics that AMCA fan classes are based on?
22. What are the two broad types of fan designs?
23. What is the difference in operating characteristics between centrifugal fans with forward-curved blades and centrifugal fans with backward-curved blades?
24. Explain how a centrifugal fan moves air.
25. List the two main types of fan drives.
26. What speed does a fan need to turn to increase its airflow from 800 CFM to 1,000 CFM if the original speed is 230 rpm?
27. What happens to the amp draw of a centrifugal blower motor if the airflow to the blower is restricted?
28. What is an "air-over" motor?
29. What is the most common fan used in residential air conditioning?
30. Why should a current reading be taken anytime a belt or pulley adjustment is made to a belt-drive fan?

UNIT 76

Single-Zone Rooftop Unit Installation

OBJECTIVES

After completing this unit, you will be able to:

1. apply the manufacturer's installation instructions to the proper locating of a rooftop/package unit.
2. select the proper clearances around and above the rooftop unit.
3. evaluate the roof structure for proper weight-bearing capabilities.
4. follow instructions on how to install a roof curb adaptor for a rooftop unit.
5. perform the correct hookup of the utilities through the curb.
6. design and install the condensate drain.
7. follow directions on installing the vent hood.

76.1 ROOFTOP UNIT INSTALLATION

The rooftop unit is only as good as its installation. The majority of rooftop units are packaged systems. The longevity, operation, and servicing of the rooftop unit depend on how well the unit is installed relative to the manufacturer's installation recommendations and common sense. If the rooftop unit is installed improperly, the system will not work according to its design specifications or only marginally at best. Improper operating conditions will lead to a shorter lifespan for the unit. Poor installation practices also make it more difficult to service the unit, can create unsafe work conditions, and can possibly lead to property damage.

SAFETY TIP

Safety precautions should always be taken whenever accessing a rooftop unit. Ladders are normally used to gain access to the roof. Only occasionally will there be stairs in a stairwell that will grant roof access. The base of the ladder should be placed the correct distance from the roof. A general rule is for every 4 ft the ladder is extended, the ladder's base should be 1 ft away from the wall it is leaning on. Another technique is to set up the ladder placing your toes at its base. Standing straight up with your arms extended, you should be able to touch the ladder rails with the palms of your hands.

The ladder should extend at least two rungs above the roof, which should be about 3 ft. The ladder should be secured at the top to keep it from blowing down in the wind. This would leave you stranded on the roof, and the falling ladder could cause damage to objects or people below.

The ladder should also be inspected periodically to make sure it is sound. As an example, ladder rails can become worn from constantly rubbing against the

ladder rack on the service van. This might not be noticed without careful inspection. A ladder in this condition may be set up correctly but collapse under your weight as you begin to climb it, leading to serious injury.

Pay special attention to the following rooftop installation considerations:

- Unit location
- Clearances
- Roof support: whether the roof is strong enough for the weight of the unit
- Rooftop curb choices and installation
- Electrical specifications and hook-up
- Gas piping, if gas heat
- Condensate drainage
- Venting if a gas heat unit

76.2 UNIT LOCATION

Installation of a rooftop air-conditioning/heating unit should conform with the manufacturer's recommendations and all local and national codes, such as the National Electric Code, the National Fuel Gas Code, the Uniform Mechanical Code or the International Mechanical Code.

Considerations must be given for rooftop units so they are not subjected to unduly harsh environmental conditions that could cause corrosion of the metallic parts of the system. Examples leading to corrosion would be salt spray near seacoast areas and fumes or mists from nearby manufacturing facilities. If the unit is to be located in a seacoast area, it should be sheltered from the predominant ocean wind direction. This may be difficult, so one option may be to install the unit on the ground if that is a better choice than the roof (Figure 76-1).

If fumes or mists are present, locate the unit in the best possible place relative to their source. Offending smells can also create a problem. Some outside air is always required, and the amount will depend on the application. Location of the unit is important so objectionable smells are not introduced to the conditioned space.

(a)

(b)

Figure 76-1 (a) Rooftop unit installed on the ground; (b) rooftop unit installed on the roof.

TECH TIP

The location and orientation of a rooftop unit on a shopping mall installation should include an assessment of the exhaust vents and makeup-air vents for other units located within the same general vicinity. It is important to avoid installations that can lead to such things as hot-dog-flavored dresses in a clothing store or loading dock truck fumes in a sporting goods shop.

If the rooftop unit cannot be installed in a favorable location away from contaminants, then frequently wash the coils, cabinets, and fan blades. This washing will slow down any corrosive effects. The condenser coil is the component most likely to be subject to the damaging effects of corrosion eventually affecting the operation of the unit. There are aftermarket coatings that can be applied to reduce corrosion. However, always check with the manufacturer before making any modifications to the equipment so as not to void any warranties.

Another factor to consider in locating the rooftop unit is water runoff. A poor location increases the risk of water leaking into the building. Choose a location least affected by rain and water runoff. Visual inspection of the roof after a rainfall would be one way of determining a good location. Check for any standing water puddles on the roof. For a new construction project, the building plans should be consulted. There will always be limitations to where the unit can be installed as determined by access to ductwork and utilities.

The unit should be installed high enough off the roof to prevent water from collecting in the unit itself. If it is ducted from the side, place it on 4×4 treated wood posts cut to fit the length or width of the unit. Generally two or three posts will be necessary to support the unit properly, depending on the size of the system. A transition of some kind, such as a piece of felt or tar paper, should be placed between the wood and the roof. The rooftop unit should be set on a roof curb if the system utilizes a duct return and supply.

TECH TIP

When deciding on the location for the rooftop unit, keep in mind that a crane will be picking the unit off the ground and setting it on the roof. Cranes will have a maximum distance they can reach out over the edge of the roof. If the designated location is too far from the edge of the roof, the crane cannot be used to move it all the way. Some other means will have to be considered for the final positioning of the unit. In this case, use the crane initially for setting the unit down on a dolly or on round posts. If posts are to be used, then simply push the unit and the posts will roll with it. As the unit rolls off the last post in line, move that post to the front to keep the process going.

76.3 LEVELING THE UNIT

The rooftop unit has to be installed in a level position. This is so condensate collecting from the evaporator cooling coil surface drains properly. On a flat roof, leveling the unit is typically not much of a problem. A level placed on the unit can be used to check that it is setting properly. When a curb is utilized, it must be leveled during its installation. If treated wood posts are used, make sure they create a level platform before setting the packaged unit on them. When the unit is to be set on a sloped roof, other considerations will have to be made. Build a platform, usually made from steel, to keep the unit level on a sloping roof.

76.4 CLEARANCES

Maintain proper clearances around the rooftop unit. This allows for proper condenser airflow, room for service, room for a possible economizer, room for the proper exhaust venting from a gas heat unit, room for side duct connections, and room for electrical and gas connections.

Clearances will vary by manufacturer and style of unit. Typical manufacturer's recommendations call for at least 60 in of clearance above the condenser fan to prevent recirculation of air back into the condenser. A clearance of 60 in is common for most air-conditioning units if the unit has top discharge. Maintain an 18-in clearance around the condenser. Maintain a 48-in clearance in the front to access controls.

Another issue related to clearance is snowfall. Make sure the unit is set above the highest anticipated snowfall for the geographical location. This is important for proper venting of flue gases and flow of combustion air when a gas heater is utilized. If a heat pump rooftop unit is used, then the outdoor coil has to be above the highest anticipated snowfall for proper airflow through the coil.

TECH TIP

While servicing a rooftop unit, care must be taken not to damage the roof. When panels are removed to access electrical or refrigerant connections, make sure the panels are secured. Unsecured panels can become dangerous flying objects when blown by the wind. Also be careful with the corners of panels when setting them down, as these can damage the roof. A worst-case scenario is for inside water damage from a heavy rain shortly after the unit has been serviced. This most likely indicates that the roof was damaged due to poor maintenance procedures.

76.5 ROOF SUPPORT

Roof strength has to be considered when installing a rooftop unit. First determine if the roof is strong enough to support the weight of a rooftop unit. The weight of the unit can be found in the manufacturer's installation instructions. The total weight will depend on the size of the unit. Some examples are as follows:

- Rheem 180,000 BTU of cooling—1,702 lb
- Rheem 240,000 BTU of cooling—1,796 lb
- Lennox 60,000 BTU of cooling—535 lb
- Rheem 36,000 BTU of cooling—520 lb
- Lennox 36,000 BTU of cooling—355 lb

Once the weight of the unit is known, consulting with the architect or an engineer may be required to determine if the roof is strong enough for a particular unit.

SAFETY TIP

The weight of the rooftop unit will have to be known to make sure the proper size crane is used to set the unit on the roof.

Figure 76-2 Typical roof curb dimensions and openings.

76.6 ROOF CURB

When the installation requires a roof curb, follow the installation instructions to install the curb properly and safely. The correct curb has to be matched to the rooftop unit (Figure 76-2). Normally the manufacturer supplies the correct curb for a particular rooftop unit, but when replacing an existing rooftop unit with another brand and/or size of system, a roof curb adaptor may have to be used. Replacing an existing roof curb should be avoided to preserve the integrity of the roof.

The roof curb from the manufacturer may come unassembled, but even so, field assembly is still relatively easy. Matching up the correct sides and inserting corner brackets will typically connect them together. In some cases, the curb will be a generic one that will fit different sizes of packaged units. With these, the curb package will come with rails to attach to the inside of the curb frame, relative to return-air and supply-air openings. Consulting the installation instructions makes putting things together simpler than guesswork.

For a new construction project, the roof curb should be delivered and installed (per installation instructions) in the chosen location when the rafters are up and before the roof is decked. This allows for the curb to be flashed and installed as an integral part of the roof.

The typical design for roof curbs is as follows:

- The heights of the curbs may vary with manufacturers. An example would be a 14-in or 24-in curb, depending on how high the unit needs to be off the roof.
- The curb, when put together, is normally in a rectangular shape to reflect the shape of the rooftop unit.
- The top of the curb will be flat all the way around. The rooftop unit will set on top of this flat spot and have a lip that extends down and on the outside of the curb (Figure 76-3).
- Use a gasket material between the rooftop unit and the curb to prevent water leakage, which would flow inside of the structure.
- The rooftop unit is secured to the curb by some means, such as screws.
- The roof curb will generally have a nailer strip around its top edge for the roof flashing to attach to.
- The bottom of the curb will have a 90-degree turnout that would set on the frame of the roof and that the roofer would set the decking on top of.
- The curb will have rails that are positioned inside the curb relative to how the ductwork will be installed. If

Figure 76-3 Cutaway view of a roof curb.

the duct comes out of the sides of the rooftop unit, then this position is not critical. If the ductwork is to come out of the bottom of the unit, then the rails will have to be set accordingly.

- The curb may have insulated panels that will be set between the rooftop unit and the portion of the curb under the condenser.
- The roofer provides counterflashing, insulation, and cant strip, which all go on the outside of the roof curb.

The roof curb has to be installed square to the roof relative to the roof joists. The purpose is so that the plenums, when dropped into their correct positions, will line up with the roof joists. Once finished and the curb is set, the building will most likely still be in the rough-in phase of construction. Therefore, the rooftop unit will not need to be set in place until later in the construction process. If that is the case, close off the top of the curb with plywood or sheet metal. This prevents water from leaking into the structure.

The advantage of installing the curb on a roof during the construction phase should now be apparent. No holes for the return- and supply-air plenums must be cut into the roof. The roofer simply decks to the curb, insulates around the outside, applies flashing, and installs the cant strips along the bottom edge of the curb. The roof is finished with whatever material is used as a sealant, leaving the portion of the roof inside the curb open.

For installation on an existing roof, holes have to be cut through the roof for the return-air and supply-air plenums. This can be a complicated procedure. Concrete roofs require special concrete saws. If the decking is wood, then the procedure is slightly easier. However, no matter the roofing structure, consideration should be given for subcontracting this portion of the installation to a roofing company. They normally have the proper tools to penetrate a roof, whatever the material. Once the holes have been cut through the roof for the plenums, the curb is placed into position, and the roofer takes care of the flashing and sealing.

When preparing to set the rooftop unit, first the plenums are installed through the roof curb. The plenum's open end will have a lip around the edge, and this lip will rest on rails laid in position. Gasket material is placed on the top edge of the curb, and the rooftop unit is lowered onto it (Figure 76-4). Generally a crane company will be contracted

Figure 76-4 (a) Rooftop unit, curb, and gasket; (b) exterior view of rooftop unit; (c) air flow through the filter and down through the opening in the rooftop unit to the building's duct system.

to pick the unit up, move it over the roof and above the curb, and lower it down and into place.

SERVICE TIP

Before the rooftop unit is set, always check the level of the curb.

76.7 CURB UTILITY PENETRATIONS

Another key aspect of setting the rooftop unit is the consideration for utility connections. Some of the utilities that a rooftop unit may require are high-voltage wiring to run the fan motors and compressor or compressors, wiring for electric strip heat if the unit utilizes electric heat, low-voltage wiring for connecting the thermostat to the package unit, and a gas line if the system has gas heat. Rooftop units normally have openings in their bottom pans to match the openings provided in the roof curb. Electrical connections can be brought in from the building and connected to the unit through these openings.

Utility penetrations may also come directly through the roof outside the roof curb, but this type of setup offers more chances for water leaks. One important point to remember is that all electrical connections have to follow the National Electrical Code. In addition, local and state laws will dictate what utilities the HVACR installer/service technician can run and hook up. Also, what licenses the HVAC company holds will determine what work the HVACR installer/service technician can do.

TECH TIP

License requirements vary from state to state. License law and codes dictate what parts of the heating and cooling system the HVACR installer/service technician can hook up. Certain portions of the electrical and gas installation can be performed by the HVACR installer/service technician, while some parts of the installation cannot. If in doubt, contact the local code officials or state license law officials.

On a new installation, the voltage requirements of the unit must be determined so the electrician can connect the proper supply voltage for the unit. Voltages available vary and may be 208–240 V single-phase, 208–240 V three-phase, or 460–480 V three-phase all at the same location. If an existing rooftop unit is to be replaced, then the new unit will need to match the voltage currently used, unless another voltage is available. Installing a new unit with a different voltage or phase would increase the cost of replacement. It is also important to note that a balanced three-phase circuit means more than just a voltage balance. It also includes a balance of frequency and sine wave, which can be tested with some higher-end meters.

The high-voltage circuit from the main electrical panel should be wired to the disconnect switch mounted on

the rooftop unit. This gives the service tech an easy and quick way to disconnect the unit from its power source. Some manufacturers will provide a bracket to attach to the rooftop unit, and the electrical disconnect will attach to it. The main thing is that the electrical disconnect must not block access to any part of the rooftop unit that might need servicing. From the electrical disconnect, the high-voltage wiring normally goes through flexible or rigid conduit and connects to the contactor in the service panel inside of the unit.

Low-voltage wiring will have to be run from the unit down to the system thermostat. The thermostat should be positioned at a central location in the conditioned space, close to the return air if possible. The return air is what the thermostat should be monitoring. Thermostat locations to be avoided are those that may be influenced by blowing supply air, drafts from doors to the outside, or direct sunlight. The thermostat should be mounted approximately 5 ft high.

If the unit utilizes resistance heat, then a separate electrical circuit may have to be wired into the heating package. (The manufacturer's installation data should be consulted for proper field wiring of the low- and high-voltage circuits.) Proper wire size is a must. The size of wire is dependent on the load demand. (Manufacturer's data can be consulted for minimum and maximum ampacities of their systems, which can be used to determine proper wire sizes.) Voltages should not vary more than 10 percent from nameplate data. If the rooftop unit is three phase, then the phases must be balanced within 3 percent. This means that the voltage between any two power leads has to be within 3 percent of one another.

76.8 GAS PIPING

If the unit utilizes gas heat, then a gas line will need to be connected to the rooftop unit's gas valve. A gas stop valve must be installed in the line ahead of the rooftop unit's gas valve. In addition, a regulator to reduce the pressure will have to be installed, unless there is a regulator installed on the ground at a different location.

SERVICE TIP

Before opening the gas stop valve, make sure the gas pressure has been reduced from the main line pressure. Gas pressure should not exceed 10.5 in wc at the gas valve for natural gas. If it is higher than this, damage will likely occur to the gas valve.

The gas line should be sized to prevent any undue pressure drop. A drip leg has to be installed in the gas line as close to the unit as possible. This provides a place for sediment and moisture to collect and is easy to clean out. It also can be used for measuring the gas supply pressure (Figure 76-5). The manufacturer's installation instructions should be consulted to determine the proper pipe size gas line for the capacity of the unit.

Figure 76-5 (a) Measuring gas supply pressure at the clean-out connection with a manometer; (b) rooftop unit with both a gas line and a condensate line.

76.9 CONDENSATE DRAIN

Part of the process of air conditioning is moisture removal from the air for dehumidification. The evaporator coil is below the dew point of the air being conditioned. Water in the air condenses on the cold coil and follows the fins down into the drain pan located beneath it. From there, the condensate drains out into the drain line through the drain connection.

For this drain process to work properly, the condensate drain line should have a trap installed in it. The trap serves a couple of purposes. One is to prevent insects from finding their way into the rooftop unit, where they could then enter the structure. The other purpose is so the condensate will drain properly.

Figure 76-6 Condensate trap. (Copyright Climate Master, Inc.)

Many packaged/rooftop units have draw-through evaporator coils. The blower is located downstream of the evaporator coil and creates a negative pressure across the coil. Therefore, the drain will also be at a negative pressure whenever the blower is running. This can prevent the condensate from draining properly. A water-filled trap installed in the drain line will provide an air break. Because of the trap, water will not be pulled back up through the drain while the blower is running. There are also many examples of older units where the evaporator coil is located in the discharge airstream. In this case, the primary function of traps is to prevent the cooled air from escaping the unit and being wasted.

When trying to decide the best way to design a trap, you should simply follow the recommendations of the manufacturer. Normally a schematic with the proper drain trap dimensions is provided with the unit (Figure 76-6).

Although a condensate trap is a necessity, it can also create problems. One of these is the possibility of freeze-up. There will be instances when the rooftop unit may be cooling in the afternoon but by morning the outside temperature has dropped below freezing. The condensate trap full of water from the cooling cycle will freeze and split. Now there will be a problem during the next cooling cycle. If this is a common occurrence, corrective steps can be taken. The trap can be insulated, and if necessary heat tape can be installed around the outside of it.

Another problem with drain lines on rooftops is that they are exposed to ultraviolet radiation from the sun. UV light will break down PVC pipe. One way to correct this condition is to insulate the pipe. Another option is to use an alternative piping material, such as copper tubing. However, this is generally a more expensive remedy.

SERVICE TIP

When installing the drain line for a rooftop unit, attention to detail will guarantee proper condensate removal. If the drain line is going to be run a considerable distance, an air vent should be installed. The location for the vent is important. It should be placed right after the trap at

the point where the condensate exits. The vent will help prevent vapor locking of the water in the drain. It is also important to correctly pitch the drain line away from the unit, typically a 1-in drop for every 10 ft of distance. There should also be no dips in the drain line.

76.10 VENTING

Rooftop units can be manufactured with cooling only or with cooling/heating. If the unit has electric heat or is a heat pump, there are no considerations required for proper venting or combustion air supply. If the unit has gas heat, there needs to be accommodation for venting and combustion air. Before the introduction of forced-draft or induced-draft rooftop units, the heating part of the unit was vented from the top through a vent pipe and cap. These older-model rooftops used standing-pilot ignition systems, and nuisance blowouts of the pilot occurred frequently. Most of the units used today, which are forced- or induced-draft systems with automatic ignitions, use only an exhaust/combustion air inlet hood. The exhaust/combustion hood normally comes with the unit uninstalled. After the initial setting of the rooftop unit, the hood is screwed into its proper place.

UNIT 76—SUMMARY

There is nothing that can replace the experience gained from working in the field, but even an experienced technician must still keep abreast of changes in installation procedures and equipment design. Reading current literature and trade journals, attending seminars and training sessions, and referring to the manufacturer's installation instructions are the keys for the HVACR installer/service technician to stay current with installation procedures. HVAC equipment manufacturers want their equipment installed correctly and operated properly and safely.

There are a number of important considerations to be taken into account when installing a rooftop unit. The strength of the roof to support the HVAC unit needs to be determined. The proper location of the unit has to be selected to minimize the chance of water leakage into the building and to avoid damage from corrosive, poor-quality outside air conditions. Proper voltage and phasing must be applied to the unit. Drain lines must be installed correctly for proper condensate removal. Clearances on top and around all sides of the unit must be adequate for correct operation, safety, and servicing. The correctly sized roof curb must be installed correctly.

Installing a rooftop unit is a multistep process. Any one improperly completed step can lead to poor performance from the system and premature failure of the unit. The manufacturer's installation instructions the relevant codes, and the use of common sense, will go a long way in making sure a rooftop HVAC system runs like it was designed and in providing the customer with what has been paid for.

WORK ORDERS

Service Ticket 7601

Customer Complaint: Water Dripping Through Ceiling Tile

Equipment Type: Rooftop Package Air-Conditioning Unit

A business customer calls in a problem complaining of water dripping through the ceiling tile. There has not been a rain in several weeks, so the rooftop air conditioner is suspected. The service technician gets the call and arrives, goes inside the establishment, and locates the ceiling tile with the water damage and drip. Now the service technician has a good idea of where on the roof to start looking for the leak. Setting up a ladder and buckling on a tool belt, the technician climbs onto the roof. Just as suspected, a rooftop unit is directly above the spot in the ceiling where the leak is.

It is a spring day, warm and humid. The service technician knows the air-conditioning unit will be condensing a lot of water from the air being conditioned. The condensate trap is found lying on the roof, detached from the main drain leaving the unit. It looks as though the trap broke at about the middle of an elbow, probably due to water being still in the trap and freezing during the winter.

The air conditioner is running, and the service technician hears the condensate gurgling as it tries to drain out, but the negative pressure will not allow it. The service technician takes the panel off of the evaporator section and secures it. The condensate is flowing over the edges of the drain pan and through a gap between the return duct and the roof curb. Then the condensate is spilling down through the attic and on top of the ceiling tile.

The service technician installs a prefabricated trap to replace the damaged one. To help prevent the freezing problem from occurring again, the technician insulates the trap. Following the condensate drain line down along to the roof drain, the technician sees a steady stream of water running into the roof drain. The inside of the unit is checked one more time to make sure the condensate drain pan for the coil is not overflowing. The service technician reinstalls all panels securely and cleans up.

Service Ticket 7602

Customer Complaint: Compressor Noise on Start-up

Equipment Type: 3-Ton Rooftop Packaged Air Conditioner

The 3-ton rooftop unit's installation is complete. It is now time to start the unit up. With the correct panels removed, the service technician has the proper refrigerant gauges installed and a voltmeter ready to check voltages. A clamp-on ammeter is placed around one of the power leads to the contactor. The system is a three-phase, 240 V unit.

The service technician does one more check to make sure all the wiring has been done correctly. Taking out a

set of jumper cords, the technician carefully jumps R to Y and R to G and then turns on the disconnect switch. The compressor contactor and fan relay energize. The blower comes on correctly, the condenser fan begins running, and the compressor starts up, but it makes a terrible noise. The service technician looks at the gauges and notices that the suction pressure does not drop like it should if the compressor were pumping.

The unit is equipped with a scroll-type compressor. Quickly turning off the electrical disconnect, the service technician notes that the compressor scroll is orbiting backward. The scroll compressor will only compress refrigerant if the rotor is running in the correct direction. The service technician disconnects two of the high-voltage leads from the contactor and reverses them, tightening them securely. The disconnect switch is then turned back on and the unit starts up and begins running normally. The compressor runs smoothly, and the suction pressure starts to pull down like it should.

Service Ticket 7603

Customer Complaint: Several Offices Warmer than Usual, Unit Not Cooling

Equipment Type: Rooftop Air-Conditioning Unit

The building manager calls in and explains that several offices are running warmer than usual. Contacted by the dispatcher, the service technician heads out to the location. This is a new account, so there is no record of what kind of equipment will be involved. The only information received from the dispatcher was a no-cool call, an address, and who to talk to.

Arriving on the job, and after finally locating the right contact person, the service technician finds out which offices are having problems. The HVAC unit is located on the roof. The service technician correctly sets up a ladder, buckles on a tool belt, and climbs up the ladder to the rooftop unit. The unit is running, so the disconnect switch is shut off to remove power to the unit.

The service technician pulls the panel to access the refrigerant service ports and secures the panel. The service port caps are unscrewed and a gauge manifold with low-loss fittings is installed. The panel providing access to the evaporator coil is next removed and secured. One temperature thermister is positioned in the return air and another in the supply airstream. The service technician puts this panel back in place, so the airflow is correct through the coil. A temperature probe is positioned on the suction line about 10 in before the line enters the compressor.

The service technician then powers the unit back up. All components seem to be running, so the panel removed to access the service ports is put back in place. If this panel is not in place, then the airflow would be around the condenser coil and not through it.

After the unit has run about 10 minutes, the service technician takes some readings. The discharge pressure

appears to be reasonable for R-22 at 275 psig, as the outdoor ambient temperature is 94°F. The suction pressure of 80 psig is high. The service technician then checks the temperature difference across the evaporator coil, and it is 10°F, which is too little. Upon further investigation, the service technician can feel hot air being pulled in from a gap between the rooftop unit and the curb. The evaporator coil cannot overcome the 94°F air that is being pulled in from the roof.

This is a job for the installers to fix. The service technician calls in to the dispatcher and fills in the details. The dispatcher says an installer will be over right away.

UNIT 76—REVIEW QUESTIONS

1. Describe one method to determine if a ladder is correctly set up.
2. Besides the manufacturer, where can the rooftop unit installer consult for proper unit installation?
3. If the rooftop unit is installed in a seacoast area, what is one consideration as to its location?
4. If the rooftop unit is subjected to a corrosive environment, and cannot be installed in an area away from the offending corrosion, what would be a possible alternative?
5. What is one of the main reasons the rooftop unit has to be level?
6. Proper clearances are required for what purpose concerning the condenser?
7. What are the two possible duct configurations for a rooftop unit?
8. If using a heat pump rooftop unit, why is proper height off of the roof important?
9. Why must the technician secure the rooftop unit's panels when servicing the unit?
10. Where can the weight for a rooftop unit be found?
11. The gasket material used between the rooftop unit and the roof curb is used for what purpose?
12. Why is it important for the roof curb to be square with the roof joists or rafters?
13. Utilities can be run to the rooftop unit in what two ways?
14. What code specifies the correct way for electrical connections to be made?
15. When installing units requiring three-phase power, what is one of the concerns with the three-phase installation?
16. What process allows for condensation of moisture on the evaporator coil?
17. What must be installed in the drain line to ensure proper condensate removal?
18. If PVC pipe is used for the construction of the drain line, what must be done to prevent deterioration of the pipe, and what causes this deterioration?
19. If the rooftop unit utilizes gas heat, what two processes have to be considered in the installation of the unit?
20. What is the customer's number-one concern relative to the rooftop unit?

UNIT 77

Zoned Systems

OBJECTIVES

After completing this unit, you will be able to:

1. explain how the outside air supply to a conditioned space is normally controlled.
2. identify the differences between air-distribution systems for core cooling as compared to perimeter cooling applications.
3. describe how a constant-air-volume system is normally configured.
4. explain how a variable-air-volume multiple-zone air system is normally configured.
5. explain how an energy-recovery wheel operates.

77.1 INTRODUCTION

Air-distribution control systems vary depending on the type of application, building design, and zone requirements. A single space maintained at one constant temperature would require the simplest form of control system. The amount of air supplied to the space can be allowed to remain constant with the control system configured to control the air temperature through the air handler. The duct static air pressure and the load on the supply fan remains relatively constant.

A large multistory building will have conditioned spaces of all different sizes. Some of these will be in the center core of the building, while others will be around the outside located in the outer perimeter. The heating and cooling demands for one space will vary from another. For these reasons, a building of this type will require more complex control systems. Each space may require its own terminal unit with dampers that are adjusted to meet the individual space temperature requirements. As the position of air dampers changes throughout the system, the duct static pressure and loading of the supply fan also change. Variable-frequency drive supply fans can be used that allow for speed variations to offset the changing duct static pressure.

77.2 AIR HANDLING

A typical air-distribution system is shown in Figure 77-1. This circuit has many different components. In tracing this circuit, we will start at the entrance to the air-handling unit (AHU). Air that enters the unit is made up of both return air from the conditioned space and outside ventilation air. In the AHU, air passes through the filters, preheater, cooling coil, heating coil, reheater, and finally the fan. This type of system is referred to as a draw-through system because the fan is located after the coils and draws the air across them. A blow-through system would locate the fan before the coils.

Outside Air Supply

The air entering the air handler will be a combination of outside air mixed with return air from the space being

conditioned. If only outside air were used, the load on the heating or cooling system would be excessive. To conserve energy, the outside air supply can be regulated to a minimum amount. Normally, the outside air supply is never completely shut off because some fresh air should always be supplied to the space. The amount required typically depends on the number of people occupying the space and the usage of the space. As the amount of outside air is reduced, the carbon dioxide (CO₂) levels in the space will increase (Figure 77-2). An air-quality sensor can be installed in the conditioned space or the return-air duct to detect levels of CO₂ in the air. The sensor can be used as an input for control of the outside air damper. This allows only enough outside air to maintain the proper air quality while not oversupplying outside air, which would increase the total energy demand.

TECH TIP

Generally some outside air is always supplied to a space, but there are exceptions for fire containment. Fire dampers close off the supply of outside air completely so that the fire is not fed any additional oxygen. There are also exclusive systems for special applications that totally shut off the supply of outside air in the event of chemical or biological attack. These dampers should not interfere with normal operation.

Filters

Filters may vary greatly depending on the building type. On packaged air handlers, disposable filters are often used. As the filters become dirty, the airflow will become restricted. This can lead to increased energy use due to inefficient system operation. A filter status differential pressure switch can be used to trigger an alarm when the filters become dirty. Filter manufacturer literature should supply information on the differential pressure limits for dirty filters. Generally, the differential pressure is set from 0.05 to 2.0 in wc, depending on the filter and system type.

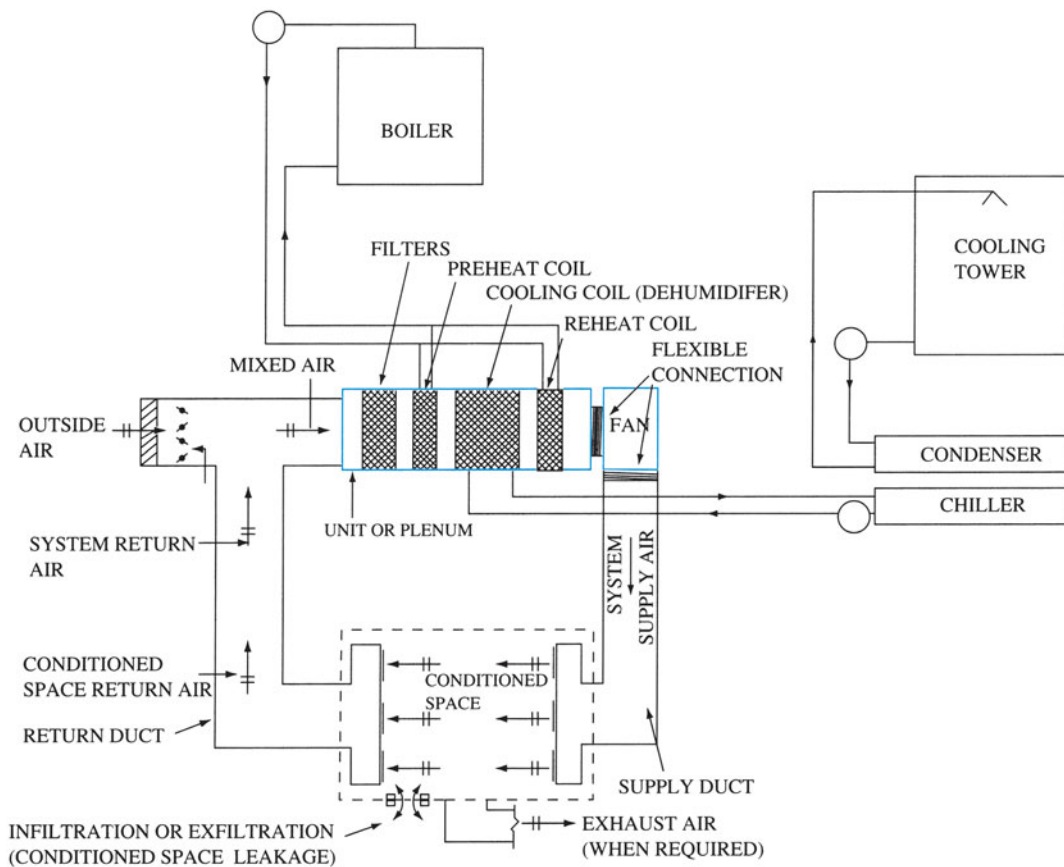

Figure 77-1 Typical central HVAC system showing air handling unit (AHU).

Cooling Coil

Cooling coils are typically direct or indirect expansion. The evaporator for a direct expansion system is directly in the air stream. The evaporator for an indirect expansion system is in a chiller, which cools a secondary refrigerant. The secondary refrigerant is circulated to water coils located in the air stream. The heat from the air gets to the refrigeration system indirectly, through a secondary refrigerant. The control of air temperature when using direct expansion coils is accomplished by regulating the refrigerant flow through the coil at the inlet. Coils may have multiple expansion valves and be staged to supply more or less cooling depending on the final air temperature. Indirect expansion coils use chilled water and typically the air temperature is controlled by regulating the water flow through the coil at the outlet. Face and bypass

dampers can also be used to vary the airflow across the coil as an added control of the air temperature.

Preheater

The preheater is located in the airstream before the cooling coil. With indirect expansion chilled-water coils, there is always a possibility of the coil freezing during cold weather conditions. This is because no matter how cold it may become outside, some outside air needs to enter the space for proper air quality. The low air temperature could freeze the water inside the coil, causing it to split and then leak. The coil would need to be repaired or replaced. To avoid this situation, one option is to drain the chilled water loop every time the outside air temperature drops, but this would be impractical. More commonly, preheaters are utilized. These

Figure 77-2 Ventilation air based on CO₂ setpoint.

may be electric, steam, or hot water. The preheater will turn on when the incoming air drops below a preset temperature. This should be well above the freezing temperature of the coil, which may vary from system to system depending on the amount of glycol added to the chilled-water loop. In addition to protecting the cooling coil from freezing, the preheater also provides some heat to the conditioned space.

TECH TIP

Preheaters are used to prevent the cooling coil from freezing. Many systems also include a low-temperature switch as a backup that will turn off the fan if the air temperature becomes too low.

Heating Coil

Heating coils may be electric, steam, or hot water. Electric heat is the most expensive but also the simplest. Hot water is also very common on small commercial systems. Many furnaces in this size category are forced hot air or hot water rather than steam. Hot-water heating coils are also simpler and easier to control than steam coils. However, steam coils provide for increased heat transfer for large-capacity systems and are preferable if an adequate steam supply is available.

Reheater

Reheaters can be electric, steam, or hot water. These are used on systems that require increased dehumidification. In geographical locations of high humidity, the air drops down below its dew point temperature as it passes across the cooling coil. The water vapor in the air will condense and be collected and drained away as condensate from a pan beneath the cooling coil. Although moisture has been removed from the air, it is now cold with a high relative humidity and will create drafts that could be uncomfortable for the people in the space. The reheater will increase the temperature of the air and reduce its relative humidity to more comfortable levels. This type of system is inefficient because the air is being cooled, which requires energy, and then it is heated back up again, which requires additional energy. Instead of this form of reheat, it is preferable to use the warmer return air or outside air mixed with the cold air supply rather than a separate reheater whenever practical.

TECH TIP

In older building design, zone reheaters were used to control the final temperature of individual conditioned spaces. As an example, in a central system, the air supplied to multiple spaces will be at the same temperature. However, individual thermostats can be used for each space. If a person is too cold in one space then he or she can adjust the thermostat setting. This does not affect the central system but only the reheater, turning it on for that particular space. Due to current energy codes, these types of systems are no longer used.

77.3 AIR-DISTRIBUTION SYSTEMS

For simplicity, types of commercial air-distribution may be classified as low-, medium-, or high-velocity systems. The required velocity of the air is dependent on the length and configuration of the duct system along with the flow rate required for the space. Cool air is admitted to a space to absorb heat, thereby maintaining a comfortable temperature. The amount of cool air (i.e., the flow rate in CFM) required will depend on the total cooling load for the space (how much heat will need to be absorbed). Velocity should not be confused with flow rate. A large axial fan used for ventilation can deliver high flow rates of air, but this would be at a relatively low velocity. For a given flow rate (dependent on cooling load), if duct size decreases then the static pressure and the power required to deliver the air will increase.

Low-velocity systems are often associated with the application of smaller unitary packaged and split-system units. The use of limited ductwork or none at all (free blow) is typical of the classification. Where ductwork is used, the external static pressure is held down to the range of 0.25 to 0.50 in wc. The use of concentric supply and return ducts is a common application. The type of duct design is the same as that of the equal friction method, which permits the prediction or control of total static.

Medium- to high-velocity systems are often used in large central air-distribution systems. Smaller ducts use up less space, and this can lead to installation cost savings. With smaller ducts, the ceiling height can be lowered by as much as 1 ft. For a large twelve-floor building with 10-ft ceilings, this will mean that one additional floor can be added that would have been occupied by the total sum of each floor's duct system. Smaller duct systems also provide for added installation choices. Older buildings with narrow areas and space limitations due to the structural design of the building can be better accommodated. Despite these space and installation savings, it should be realized that high-velocity systems will have higher operating costs and higher noise levels.

TECH TIP

The higher the air-distribution system's operating static pressure, the lower the system efficiency. This is because the blower has to work harder to move enough air. To reduce the static pressure, larger ducts are required. The savings from having a lower static pressure must be balanced against the higher cost of the larger duct system.

77.4 AIR-DISTRIBUTION APPLICATIONS

Air-distribution applications in central station systems fall into three broad areas: interior or core areas, exterior or perimeter areas or zones, and entire building applications.

Core areas have conditioning loads subject only to interior loads, such as lighting, people, and equipment. Consequently, they are basically cooling-only loads, except for top floors and/or warmup cycles in extremely cold climates.

Perimeter zones are exposed to outer building skin variables, such as wall and window loads, wind effects, and exposure effects, as well as the items in the core areas. The

Figure 77-3 Single-zone system using constant volume.

perimeter zones have to handle a wide range of conditions, including such variances as high solar gain on a winter day requiring cooling, while shaded parts of the building require heating.

Entire building applications are a combination of these systems, the selection of which depends on building size and economics. Small buildings frequently cannot justify one system for the core and another for the perimeter. In these instances, any one of the perimeter systems can be used for the entire building.

The systems are all of the type that use primary (supply) air from the air conditioner, and the maximum quantity needed is based on the maximum load conditions of the area.

77.5 CORE AREA APPLICATIONS

If the interior core of a building is a large open area, a single-zone constant-volume system (Figure 77-3) can be used at a reasonable initial cost. The amount of air supplied is always the same. The desired supply-air temperature is maintained by the heating and cooling coils only. A single HEAT/COOL thermostat with automatic changeover provides year-round control of the coil temperatures. Top-floor and ground-floor systems will have heating for morning warmup. Intermediate floors usually only have provisions for cooling. The duct design follows conventional practice, with room air distribution from the ceiling.

For core areas divided into smaller spaces, with variations in lighting and people loads, a variable air volume (VAV) single-zone system has typically been used. Rather than always supplying the same amount of air to the space, the amount of air can be adjusted to better meet the load demands of the space. There are several approaches to this application.

Constant-volume fans may be used with individual VAV terminals located for each space that increase or decrease the air supply with dampers. Terminal units can be designed to control air velocity, pressure, temperature, and flow rate. The final temperature is a result of mixing airstreams of different temperatures or humidity levels. Figure 77-4 shows a constant-volume air handler connected to individual VAV terminals. The terminal may be an individual control box, a system air-powered VAV slot diffuser, or a self-contained

Figure 77-4 Single-zone system using variable air volume (VAV).

temperature-actuated VAV diffuser. In all these cases, the variable air volume is accomplished by throttling the airflow at the individual duct run, causing the constant volume air handler to “back up” the fan curve to a new balance point of lower CFM at a higher static pressure. The controls for this type of system are self-contained within the air-distribution system and do not require any more control than the thermostat noted above.

TECH TIP

Constant-volume supply fans can sometimes be used on variable-air-volume systems. However, as the demand for air decreases and dampers begin to close, the duct static pressure will increase as well as the load on the fan. This type of configuration should only be used in locations where heating and cooling loads are relatively steady.

Another approach for the core area is to use VAV terminals, with the capability of handling several duct runs from each terminal. In this case, the air handler is also constant volume, but the VAV terminal throttles the air supply to the ducts and dumps the remainder back into the ceiling-space return-air plenum. The space is controlled with variable air volume, but the air handler is operating at constant volume. The control for this subsystem requires that the space thermostat regulates an actuator on the VAV terminal, as well as the cooling and heating demand.

In either of these cases, a single air handler is sufficient in the core zone and can provide proper comfort conditions. The air handler is typically constant volume because the loads are relatively steady, regardless of the season or ambient air temperature.

An approach often seen on older systems, but prohibited by current energy codes, is commonly called zone reheat. Reheat terminals differ from this basic mixing design by controlling the final temperature of the air with hot-water coils, steam coils, or electric resistance heaters. As seen in Figure 77-5, an air handler delivers constant-volume, constant-temperature air to the distribution system. Individual zones or branches have heaters in them,

Figure 77-5 Constant-volume system using zone duct heaters.

which reheat the cool air to a comfort level for each space. These heaters may be individually controlled electric heaters, hot-water coils, or steam coils. In many cases, these heaters are applied to a problem area in a system, to provide adequate heat where the original design was insufficient.

77.6 PERIMETER ZONE APPLICATIONS

Perimeter zones require terminal systems that can handle the wide range of conditions, from the coldest morning warmup to the hottest solar gain cooling load. In many

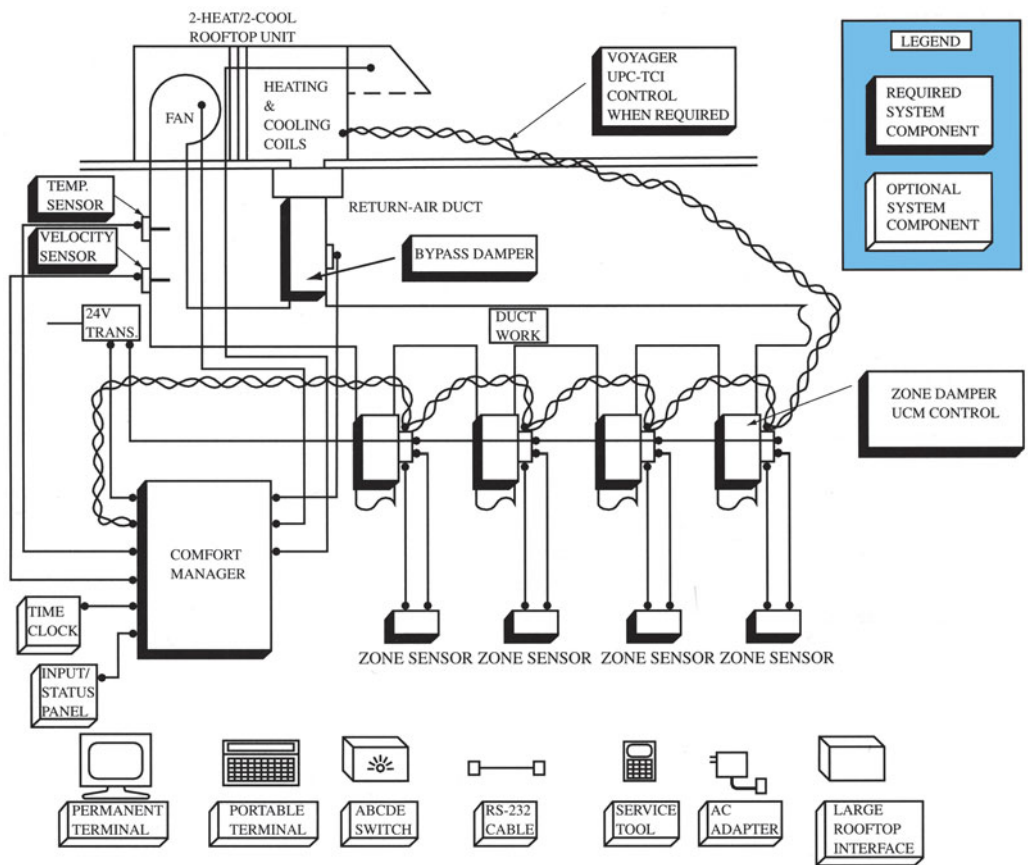

systems, this range was handled by providing perimeter-radiant or forced-air heat systems on the outer wall and under windows to furnish the necessary heat for the cold loads. A separate air system provided the necessary air movement, outside air requirements, and the cooling load responsibility. The air systems could be either constant or variable volume, but it has been found that only VAV really can provide the necessary control for comfort. In milder climates, the perimeter heating system is eliminated, without much loss of comfort.

TECH TIP

In some cases, the entire perimeter heating and cooling load will not be controlled by the central system. Instead it may be handled by console units on the outside wall, with individual outside air sources and temperature controls.

The VAV systems for perimeter applications are generally provided with primary air from either a central air handler for the entire building or an entire floor, depending on the size of the system (Figure 77-6). A single air handler may handle up to 40,000 ft² of occupied space, but in many cases the ductwork becomes unmanageable. Variable volume systems may be low velocity or high velocity, depending on the type of controller and the terminal units used. The volume of primary air is automatically adjusted to the

Figure 77-6 Schematic view of a typical variable air volume (VAV) system.

total cooling demand by duct sensors controlling fan volume controls.

The fan output may be adjusted by using variable inlet guide vanes. Throttling the air inlet to the fan will reduce the air flow during lower demand operation. This method is often used because it is more efficient as compared to reducing the airflow by placing variable vanes at the fan outlet. Reducing the air flow at the fan outlet leads to an increased static pressure. The increased pressure on the outlet side of the fan will make it work harder, and this can lead to an increase in power consumption.

Another option is for stepped speed control settings such as slow, medium, and fast. Stepped speed control and inlet guide vanes may also be used in combination with one another. However, the most efficient method is for the use of a variable-frequency drive (VFD) fan motor, which allows for the full range of speed control. VFD's are considerably more expensive than most other alternatives, but as the fan slows down under light loads, less energy is used, reducing long-term operating costs.

An older type of VAV perimeter zone system is the induction type. High-velocity primary air is delivered to induction room terminals. This saves space, since the ductwork is much smaller than conventional ducting. The terminal unit takes the high-velocity air through a nozzle arrangement, as shown in Figure 77-7. This induces room air into the unit through a heating coil. The primary air may be unconditioned, as there can be both heating and cooling coils located in the induction terminal. Figure 77-8 shows an induction room terminal that is constant volume, with temperature control achieved by reheat. Note that these terminal units do not rely on fans; the induced airflow provides the necessary secondary air.

Figure 77-7 Induction terminal.

SERVICE TIP

Induction air systems have many drawbacks. High-pressure air requires very tight and sealed ductwork, and air leaks are very noisy. These systems require considerable energy, since high duct static pressure requires increased fan power. VAV aspects are also limited because the induction effect falls off quickly with a reduction of airflow.

A type of VAV perimeter zone system operating at low pressure uses system-powered boxes or diffusers. System air-pressure controls the inflation of bladders that in turn control the air volume in the unit. These are simple in concept and effective at a reasonable cost. They provide VAV

Figure 77-8 Sectional view of an induction-type room terminal unit.

Figure 77-9 Series fan-powered variable-volume system.

space conditioning, but usually with constant-volume supply fans. Some of these diffuser units use self-contained, temperature-powered actuators to modulate the diffuser openings. These can provide fairly simple, reasonably priced VAV to smaller systems.

Other systems provide cost-effective zone control with a combination of VAV duct dampers and a sophisticated temperature control system. These allow the system to provide only heating or cooling at any given time. The demands of a number of zones are programmed to switch the system to that mode—for example, cooling. Any zones requiring heat are temporarily closed off. With a heating demand in place, the system controls will then switch the system back to heating, closing off the zones requiring cooling. The individual zone dampers are modulating, so there are no abrupt changes. A fan-speed controller is part of the system, reducing airflow to a practical minimum, as allowable. These systems are generally designed for unitary equipment, but they can be used as part of a central system.

VAV systems can be used to provide minimum airflows to meet ventilation requirements. In this type of system, the terminal units are fan powered, providing constant volume in the conditioned zone. The primary air supply will vary from 100 percent down to about 20 percent of total air requirements. The primary air handler is variable volume, constant temperature, with the cooling system demand proportional to the airflow. The low-powered terminal fan provides terminal reheat at reduced air conditions for the zone (Figure 77-9). The individual zone controls can be stand-alone systems but usually are integrated through a direct digital control (DDC) system that manages the overall operation of all terminal units.

77.7 ENTIRE BUILDING APPLICATIONS

Some older building designs utilized multizone or double-duct applications. The major limitation for this type of system is the cost of energy to provide simultaneous heating and cooling. Different types of heat-recovery methods were tried in an attempt to gain efficiency. As an example, the heat rejected from the chiller was used to provide warm water for heating. Other heat-recovery approaches have

been tried, but the fully energy-efficient approaches were not always the simplest or most economical to install.

TECH TIP

Multizone and double-duct applications were popular before energy codes were enacted; these were the ultimate in zoned comfort systems. By providing a blend of always available heated and cooled air to any zone, with the addition of good pneumatic control systems, these systems supplied excellent building comfort.

Multizone systems provide one trunk duct to each zone from the multizone air handler (Figure 77-10). The air handler is a blow-through design with a hot and a cold deck. The airflow from each of these decks is fed through a set of dampers, 90 degree opposed to each other on the same shaft. When the cooling damper is fully closed, the heating damper is fully open, and vice versa. Most of the time, the dampers are modulating in response to a temperature signal from the zone. The overall system is low to medium

**Figure 77-10** Constant-volume multizone heating and cooling unit.

Figure 77-11 Double-duct system.

pressure and constant volume. The multizone's limitations, from a design standpoint, are that only a limited number of zones are available on the air handler. Consequently, adjustments are always needed to get an even balance. The smallest zone is typically 8–10 percent of the full load.

Double-duct systems are the ultimate in design flexibility but are very high in initial cost. Double-duct systems are high-velocity, high-pressure systems. Some are variable volume, but most are constant volume. Two full-sized supply ducts are required for the system, one for cooling and one for heating (Figure 77-11). The major benefit of these systems is that the two ducts each serve one terminal mixing box, which controls the air temperature for each zone. The mixing boxes are available in very small sizes, down to 200 CFM, allowing for zones as small as $\frac{1}{2}$ ton. Zoning is limited by this small increment and the overall size of the system. The high-pressure air in the main supply ducts (4–5 in wc) is reduced in the mixing boxes, so that the distribution ducting is normally low-pressure design, with low noise levels.

77.8 MIXING DAMPERS

Dampers installed on AHUs control the flow of air through various parts of the system. The function of dampers depends on the design of the system. There are two general types of multiple-leaf dampers: parallel blade and opposing blade. Parallel-blade dampers tend to direct the air as they open, whereas opposing-blade dampers are usually constructed to more readily offer a positive close-off.

TECH TIP

The proper adjustment of mixing dampers is critical to maintaining an efficiently operating system that provides the proper air distribution within a building. Mixing dampers blend the air so that you have the proper temperature and are able to control humidity within the building. If these dampers are not set properly, the building operating cost will go up dramatically.

(a)

(b)

Figure 77-12 (a) Large air handler for central system showing location of a modulating damper; (b) modulating damper.

Dampers can operate either in two positions, open or closed, or they can be modulated so that they can be positioned anywhere between fully open and fully closed, depending on the requirements of the control system. Most dampers on central station air handlers are of the modulating type (Figure 77-12).

Dampers can be linked together, so that when one opens the other closes. For example, in a mixing box such as shown in Figure 77-13, where the return air is mixed with outside air, the dampers can be linked and controlled so that when the outside air is increased, the return air is decreased (and vice versa). This provides the control of the airflow needed for the wide variety of conditioning requirements.

77.9 MIXED-AIR CONTROL

To illustrate some of the many uses of dampers, refer to Figure 77-14. Of primary importance is the mixing of return air and outside air. During normal operation, only the return air and the minimum outside air dampers are involved. The minimum outside air damper is a two-position damper. Normally it is fully open to provide ventilation air to meet code requirements. The only time it closes is when the building is unoccupied or the system is shut down.

Provision is made in the damper system and the control system to use additional outside air for free cooling (economizer cycle) when practical. A maximum outside-air

Figure 77-13 Mixing box parallel-blade dampers.

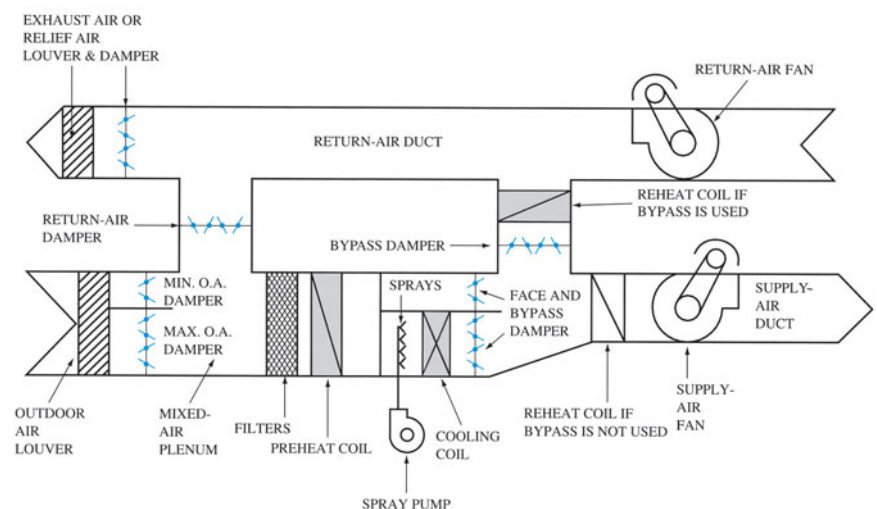

Figure 77-14 Schematic diagram of a typical AHU showing the various types of damper arrangements.

damper is modulated along with the return-air and exhaust-air damper to maintain a slightly positive pressure in the building. The total air quantity through the air handler does not change, but the proportions of outside air to return air do change to meet the control requirements.

77.10 FACE AND BYPASS CONTROL

One way to control the amount of cooling or heating is to use a face damper in series with the coil surface and bypass dampers around the coil and in a duct connection for the return air, as shown in Figure 77-14. With this arrangement, the total air volume remains constant even though the space load demand is changing. The air entering the fan can be adjusted for different load conditions by modifying the air mixture.

As an example, outside and return air are normally mixed in the air plenum chamber and passed through the filters, preheater, and cooling coil, and then to the fan. If the

outside air temperature is low enough, the face dampers on the cooling coil can begin to close while the bypass dampers around the coil begin to open. This reduces the load on the cooling coil and utilizes the outside air to assist in cooling. The damper control modulates the air quantity from each source to match the load. The two sets of dampers are linked together either mechanically or electrically so that when one modulates toward the open position, the other modulates toward the closed position (and vice versa). Because the dampers are proportioned evenly, the flow of air through the fan remains unchanged. Some systems will include bypass fans as well as dampers (Figure 77-15).

77.11 ECONOMIZER

An economizer is a mixing box assembly that will allow 0–100 percent of the supply air to be drawn in from the outside. Typically the outdoor and return-air supply vents are located in one assembly (Figure 77-16). The outside

temperature is monitored by a control system that will position the mixing damper for the most efficient operation. As an example, in the cooling mode, if the outside air is cooler than the inside air temperature, the damper will allow for more outside air to enter the building, thus reducing the total cooling load on the air-conditioning system. If the mixing damper positions allow for a high flow rate of outside air and very little return air, pressure will increase inside the building. To accommodate for this, an equivalent amount of air will need to be removed from the building by the exhaust fan.

77.12 ENERGY-RECOVERY VENTILATION

Energy-recovery ventilation is a more elaborate system for utilizing outdoor air as compared to an economizer. Energy-recovery sections often include an economizer function in their operation. However, energy-recovery ventilation not only increases efficiency but also allows for an increased amount of outdoor air to be admitted to a building. This increase in the amount of outdoor air reduces the level of indoor pollutants, as too much recirculated air can lead to an unhealthy environment. The additional load that an increased outdoor air supply places on the system can be very expensive. Energy-recovery systems allow for increased outdoor air supply without adding any considerable additional load. Systems are being designed to allow for increases in outdoor air supplies from current levels of 5 CFM up to 15 CFM per person without substantially increasing the operating costs.

The principle component for this system is often a rotating desiccant wheel that is designed to transfer water vapor and heat from one airstream to another (Figure 77-17). An energy-recovery system precools and dehumidifies the outdoor air by using the exhaust air during the summer. As shown in Figure 77-18, the return air will pass across a filter and then through the recovery wheel and out the exhaust. The outdoor air enters through a filter and then passes across the recovery wheel and into

Figure 77-18 Draw-through air-handler energy-recovery section.

Figure 77-19 Flow-through energy-recovery wheel.

Figure 77-21 Energy wheel winter condition.

the mixing chamber. Here some portion of the return air can be mixed with the outdoor air before passing on through the next set of filters and then on to the heating and cooling coils.

The principal of operation is shown in Figure 77-19. The energy-recovery wheel rotates and outdoor air passes across the top portion of the wheel while exhaust air passes across its bottom portion. During the summer months, the heat and moisture from the outdoor air will be transferred to the exhaust air. This is shown in Figure 77-20. For this particular application, the outdoor air temperature drops from 92°F to 79°F while the relative humidity still remains low. During the winter months, as shown for the application in Figure 77-21, the cold incoming outdoor air is preheated from 18°F to 59°F along with an increase in relative humidity.

Figure 77-20 Energy wheel summer condition.

Energy-recovery sections for air handlers can be configured in a number of different ways. In colder climates, frost may form and eventually block the airflow through the energy-recovery wheel. The methods for frost protection include the use of a preheat coil, a bypass for the wheel, on and off control, and exhaust only.

UNIT 77—SUMMARY

Air-distribution control systems use input from temperature, condition, and static air-pressure sensors to position dampers for directing and mixing the airflow and/or control the supply fan. Some of these inputs are also used to regulate the temperature control of the preheater, cooling coil, heating coil, and reheater. Mixing dampers can be positioned to provide for the best mix of outside and return air through the handler. Variable-air-volume systems may also adjust the fan air supply. Inlet guide vanes are sometimes used on large supply fans that can be closed to reduce the air supply or can be opened to increase the air supply. This is a more efficient way to control the airflow through a fan as compared to regulating the airflow at the fan outlet. Variable-frequency drive supply fans are becoming increasingly popular in variable-air-volume supply systems because they can be controlled to operate at the most efficient speed and load.

WORK ORDERS

Service Ticket 7701

Customer Complaint: Supply-Air Pressure Low

Equipment Type: Packaged AHU with Centrifugal Fan

The service technician answers a call for a small office building with a recently installed packaged air handler. The owner complains that the space is too hot and that there does not seem to be very much air blowing from the supply registers in each space. The system was only installed a couple of weeks ago and seemed to work properly, but the past few days the outside temperature has been very hot. The owner is wondering if maybe the unit is undersized.

The air handler is located in the back of the building, and the technician shuts off the power and then removes the access covers for the fan section. The fan seems to be mounted correctly and the drive belts appear to be tensioned properly. Turning the fan on, it runs smoothly, but it has minimal airflow. With the fan running, the technician can see the problem is in the fan rotation. It is rotating backward. The technician shuts off the power supply and reverses two of the electrical leads to the fan motor. Once the unit is restarted, the air supply is more than adequate for the system.

Service Ticket 7702

Customer Complaint: Space Too Hot

Equipment Type: Packaged AHU Unit with Direct Expansion Cooling Coil

The service technician answers a service call for a veterinary building and speaks to the office receptionist. The receptionist explains that the waiting room and the lab areas are much warmer than they should be, and this started a few hours ago. The system had been running fine prior to that. The technician is led to the back of the building where the air handler is located. The unit is rumbling and producing considerable vibration. The technician opens the access doors and immediately sees that the fan motor is loose on its mounting bolts. The unit is shut down and the drive belt tension adjusted as the motor mounting bolts are tightened. The technician replaces the original mounting nuts with lock nuts.

The unit is restarted and the vibration is eliminated and the unit is running smoothly. However, the mixing dampers do not seem to be operating. They are frozen in one position with the outside air supply almost wide open, placing a considerable load on the direct expansion cooling coil. The technician again shuts the unit down and then tries to manually stroke the dampers and finds they are not frozen into position. The lock-nut in the linkage from the actuator to the dampers

has come off due to all of the vibration. The linkage is reconnected and the actuator stroked back and forth to confirm the damper movement. Once everything seems to be all clear, the technician restarts the unit and the mixing dampers immediately modulate to their proper position, minimizing the amount of outside air through the handler.

Service Ticket 7703

Customer Complaint: No Air Supply—Space Too Hot

Equipment Type: Packaged AHU Unit with Variable-Frequency Drive Fan

The technician answers a service call for a multistory building with an air handler located on the roof. There is no air coming through the registers, so evidently the fan has tripped off. The control panel has an alarm light indicating a dirty filter. The technician finds that it is almost plugged. The filter is replaced and after resetting the fan motor overload, the unit is restarted. The measured current draw of the fan motor is high. The technician checks the fan speed with a strobe tachometer and finds that it is operating at its maximum speed setting.

The technician shuts the unit off again and locates the static air-pressure sensor. It is removed and found to be partially plugged at the inlet. The sensor is falsely reading a low static pressure, and this led to the increase in the fan speed. After cleaning, the sensor is reinstalled and the unit restarted. The fan is still running fast because of the high cooling demand on the system. As the conditioned space temperature begins to return to normal, the fan speed also begins to drop. After a few hours, the system begins to stabilize and return to normal operation.

UNIT 77—REVIEW QUESTIONS

1. Why is outside air mixed with return air?
2. How much outside air should be admitted to a space?
3. Can outside air ever be completely shut off from a space?
4. When will a preheater turn on?
5. What is the purpose of a filter status differential pressure switch?
6. Why are steam or electric reheaters inefficient?
7. What is an advantage of a high-velocity air-distribution system?
8. How does duct static air pressure affect the supply-fan load?
9. How does a perimeter heating or cooling load differ from a core load?
10. What type of an air-distribution system is a core zone most likely to have?

11. Can constant-volume fans be used in variable-air-volume systems?
12. Why are variable inlet guide vanes sometimes used for supply fans?
13. What is meant by a modulating damper?
14. What is an advantage of face and bypass control dampers?
15. What is the difference between a draw-through air system and a blow-through air system?
16. How do carbon dioxide levels relate to outside air supply requirements?
17. What are the common types of preheaters?
18. What are the three common classifications for commercial air-distribution systems?
19. What is the principle of operation for an economizer?
20. How do direct expansion cooling coils differ from indirect expansion coils?
21. How is the total amount of cool air in CFM required for a particular space determined?

UNIT 78

Commercial Control Systems

OBJECTIVES

After completing this unit, you will be able to:

1. explain how a chilled-water system operates.
2. list the common temperature input signals for a packaged air handler.
3. describe the function of air-quality and air-condition sensors.
4. describe how water or steam coil control valves operate.
5. explain the differences and advantages of different types of control systems.

78.1 INTRODUCTION

Air-handling units (AHUs) range greatly in size and application. Residential air handlers typically have a direct expansion coil and airflow rates in the range of 400 CFM per ton of air-conditioning capacity. In comparison, large commercial air handlers may have airflow rates of 55,000 CFM or greater. These units often use cooling coils supplied with chilled water from a central air-conditioning unit that may supply one or more air handlers.

Air handlers are often used for both cooling and heating. For the heating mode, smaller residential units may use electric resistance heat. Large air handlers have heating coils supplied with hot water or steam delivered from a boiler. In addition to heating and cooling, air handlers may be specially equipped to improve dehumidification of the air in the cooling mode and to humidify the air in the heating mode. Many air handlers today also can be configured with energy-recovery devices to increase the unit's efficiency without compromising comfort.

78.2 CONTROL SYSTEMS

The control system must direct the operation of all elements automatically. In large installations, the control system is usually separate from the air-conditioning equipment. Controls may be electric, electronic, pneumatic (air), or a combination of all three. The controls must be included in the initial construction stages to provide the total integration of the system.

CAUTION

Because these systems can be started and stopped automatically, you must make sure the power to the unit is off before beginning service to prevent the unit from starting while you are working on it.

Many air handlers will have an electronic control module installed in a control box located on the unit. The control module will continuously monitor inputs such as supply-air

temperature, return-air temperature, air quality, space temperature, outdoor air temperature, duct static pressure, and space humidity. Dependent on the input, the control module is programmed to control outputs such as the supply fan, cooling and heating coil valves, mixed air dampers, electric heat, and direct expansion cooling. Multiple air handlers can be configured to be linked together.

Supply-Fan Control

The supply fan can be started or stopped based upon a number of different programmable values: the time the space is occupied, the temperature of the space, an unoccupied cool-down or warmup period, and economizer cooling, dependent on outside air conditions. Fans can be a constant speed, constant volume; two-speed variable volume; or variable-frequency drive (VFD) variable volume.

Heating and Cooling Coil Control Valves

The heating or cooling coil control adjusts the steam, hot water, or chilled-water valve. Control valves are typically two way for steam and two way or three way for water. Control valves can come as normally open or normally closed. The correct sizing of proportional control valves is critical to proper system performance. An undersized valve will result in insufficient heating or cooling and damage from cavitation due to the excessive velocity through it. An oversized valve will also experience rapid wear of the seat and disk due to the increased velocity through a mostly closed valve. There will also be rapidly fluctuating temperatures and cycling (hunting), especially at light loads for an oversized valve.

A typical installation for a two-way control valve for a cooling coil chilled-water or a heating coil hot-water loop is shown in Figure 78-1. The design pressure drop across the control valve is measured with the valve fully open. The recommended maximum pressure drop for two-way and three-way valves is 35 psig. Pressure drops in excess of this value can result in cavitation, erosion of disks, or wire drawing off the seat on a steam valve. Refer to the manufacturer's recommendations or valve sizing charts when selecting new valves or replacing existing valves in the system.

Figure 78-1 Coil two-way valve.

Figure 78-2 Coil three-way valve—fails open as indicated in red.

A three-way valve installation is shown in Figure 78-2. The outlet from the coil is connected to the B port of the valve so that in this arrangement the valve will fail open, allowing for full flow. Figure 78-3 shows an opposite arrangement, where the control valve will fail closed, thereby stopping all flow through the coil.

Figure 78-3 Coil three-way valve—fails closed as indicated in red.

Figure 78-4 Heating coil steam-trap condensate-return lines.

A two-way steam control valve modulates the flow of steam through the coil based on the signal generated by the control. The pressure leaving the steam trap (system return pressure) is assumed to be zero (Figure 78-4). Low-pressure steam applications are 15 psig or less. Medium steam pressure applications operate with steam pressures higher than 15 psig. Most steam control valves are designed to operate with steam pressure not exceeding 35 psig.

78.3 PNEUMATIC CONTROL SYSTEMS

New systems are being designed today that utilize solid-state controls. However, many older systems still in operation continue to rely on pneumatic controls. System upgrades may sometimes combine both solid-state and pneumatic controls, so a fundamental understanding of pneumatic control systems is important.

In a basic control system for cooling, a thermostat sensing the chilled-water outlet temperature operates the chiller. Each air handler will have a control valve regulating the flow of chilled water through the cooling coil. The position of inlet, mixing, and bypass dampers will need to be controlled. The condenser-cooling water pump will always be operating when the chiller is running. The cooling tower fan for the condenser-cooling water may cycle, and often there may be a water bypass control.

For the heating system, boiler firing is activated by the hot-water thermostat, often referred to as an aquastat. Individual space thermostats and humidistats control the functions of the air handler.

Pneumatic control systems use compressed air to supply energy for the operation of valves, motors, relays, and other pneumatic control equipment. Consequently, the circuits consist of air piping, valves, orifices, and similar mechanical devices.

Pneumatic control systems offer some distinct advantages:

- They provide an excellent means of modulating control operation.
- They provide a wide variety of control sequences with relatively simple equipment.
- They are relatively free of operational problems.
- They cost less than electrical controls if the codes require electrical conduit.

Pneumatic controls are made up of the following elements:

- A constant supply of clean, dry, compressed air
- Air lines consisting of mains and branches, usually copper or plastic, to connect the control devices
- A series of controllers, including thermostats, humidistats, humidity controllers, relays, and switches
- A series of controlled devices, including motors and valves called operators or actuators

The air source is usually an electrically driven compressor (Figure 78-5), which is connected to a storage tank. The air pressure is maintained between fixed limits (usually between 20 and 35 psi for low-pressure systems). Air leaving the tank is filtered to remove the oil and dust. Many installations use a small refrigeration system to dehumidify the air. Pressure-reducing valves control the air pressure.

Air Dryers

Specialty compact refrigeration systems are often used as air dryers for pneumatic control systems. Figure 78-6 shows the operating display panel for an air dryer. The air is cooled as it passes through one side of a tube-in-tube evaporator coil. Then water is drained off from the air as it leaves the coil. The cooled dry air picks up heat as it leaves the unit by the warm air entering. The refrigerant cycle is typical of most systems and utilizes a compressor, air-cooled condenser, refrigerant expansion device such as a capillary tube or TEV, and a tube-in-tube evaporator coil (Figure 78-7).

Figure 78-6 Air dryer operating display panel.

Figure 78-7 Air dryer with the cover off to show the insulated evaporator coil, hermetic compressor, and air-cooled condenser.

78.4 HOW THE PNEUMATIC CONTROLS OPERATE

The controller function is to regulate the position of the controlled device. It does this by taking air from the supply main at a constant pressure and adjusting the delivered pressure according to the measured conditions.

One type of thermostat is the bleed type, shown in Figure 78-8. The bimetal element reacts to the temperature and controls the branch line bleed-off pressure. These thermostats do not have a wide range of control, therefore the

Figure 78-5 Air compressor for a pneumatic control system.

Figure 78-8 Diagram of a bleed pneumatic thermostat.

Figure 78-9 Diagram of a nonbleed pneumatic thermostat.

branch line is often run to a relay that controls the action. Bleed controls cause a constant drain on the compressed air source.
